The introduction of the endovascular approach has challenged the operative indications for intact/asymptomatic aneurysms. Indeed, the significant decrease in the perioperative mortality rate reported in both the DREAM¹⁰⁹ and EVAR Trials⁷⁹ appear to justify lowering the threshold. However, it is important to note that the rupture rate for aneurysms less than 5.5 cm in the UK Small Aneurysm⁴⁹ and ADAM¹¹⁰ Trials was <1%/yr which is still lower than the perioperative mortality rate for endovascular repair reported from DREAM,¹⁰⁹ EVAR,⁷⁹ and most of the national databases.^{73,74,111} Similarly, Finlayson et al.¹¹² used a decision analysis model to determine the optimal diameter for open and EVAR and concluded that the endovascular approach lowers the operative threshold only for older patients in poor health.

The Joint Council of the American Association for Vascular Surgery and the Society for Vascular Surgery have released updated guidelines for the treatment of patients with AAAs that address the concerns highlighted above.⁴⁸ They recommend that a diameter of 5.5 cm is an appropriate threshold for repair in the "average patient" with an intact infrarenal aneurysm, but emphasize the importance of individualizing each case. They state that rapid aneurysm expansion (>1 cm/yr), symptoms related to the aneurysm, and female gender merit repair at a smaller diameter while consideration should be given

to earlier repair in young patients provided that the operative mortality rate is acceptable. Furthermore, they recommend that a larger diameter threshold is appropriate in higher risk patients and emphasize that there does not appear to be any justification to alter the operative threshold for the endovascular approach. A reasonable approach, and one that we have adopted in our own practice, is to use 5.5 cm as a threshold for repair in men and 5 cm for women.

Patients that do not meet the threshold for operative repair should be followed closely. It is important to educate the patients about their underlying disease process and emphasize the importance of long-term follow-up. Notably, Valentine et al.¹¹³ reported that 32% of patients with small aneurysms managed by “watchful waiting” were noncompliant with their follow-up plan. Furthermore, it is important to counsel patients about the presence of symptoms associated with rupture and the importance of seeking urgent medical attention. Guidelines have suggested that patients with aneurysms < 3 cm in diameter should be re-imaged at 5 years while those with between 3 and 3.4 cm should be re-imaged at 3 years and those between 3.5 and 3.9 cm should be re-imaged at 1 year.¹¹⁴ Aneurysms > 4 cm should likely be re-imaged every 6 months. As noted above, abdominal ultrasound is likely the most appropriate imaging study for aneurysms < 4 cm with CT more appropriate above that threshold. It is important to note that up to 50% of the patients deemed a prohibitive operative risk and not offered elective repair will ultimately die from a ruptured aneurysm.^{115–119} These patients who are not candidates for elective repair should not be offered emergent repair in the event that their aneurysm ruptures or becomes symptomatic. Patients and families should be counseled on this matter preemptively to minimize difficulty and inform decisions when rupture occurs.

CHOICE OF OPEN OR ENDOVASCULAR REPAIR

After the decision to recommend operative repair has been made, the technique for repair needs to be determined. Admittedly, these decisions are somewhat interrelated since the decision to recommend operative repair in certain subsets of patients is oftentimes contingent upon whether they are candidates for the endovascular approach. The past two decades have witnessed a rapid evolution of the endovascular technique, and, indeed, this evolution has helped define our discipline. It has been clearly demonstrated that the technical success rates for endovascular graft repair are excellent and the need for intraoperative conversion to open repair negligible. The perioperative events and mid-term outcomes have been defined by level-1 evidence. Many of the technical limitations inherent to the earlier endovascular devices and anatomic limitations have been overcome. Despite the lack of definitive long-term outcome data, the endovascular approach for treatment of AAAs has been widely applied. Indeed, the endovascular approach eclipsed open repair in the United States in 2005 and recent data shows that 75% or more aneurysms are repaired in this manner.¹²⁰ The choice of open or endovascular repair is complicated and contingent upon several factors including feasibility, outcome, comorbidities, compliance, cost, and preference. It is imperative that these issues, including their respective advantages/disadvantages or strengths/weakness, be addressed with the patients during the decision process to ensure proper informed consent.

The initial determinant of the approach is the anatomic configuration of the aorta, the aneurysm, and the access vessels. The commercially available endovascular devices come in a finite range of sizes and, thus, are suitable only if specific anatomic conditions are satisfied. Although the number of available devices and their specific characteristics are constantly evolving, the “generic” endograft consists of a fabric graft (i.e., polyester or ePTFE) and a metallic endo/exoskeleton (i.e., stainless steel or nitinol) that facilitates proximal/distal fixation by the radial force of the stent (Fig. 96-7). In some devices, proximal fixation is augmented by the presence of suprarenal hooks. The “generic” devices are modular and consist of either two (main body and contralateral iliac limb) or three (main body, contralateral iliac limb, ipsilateral iliac limb) components with a variety of additional ancillary pieces that allow proximal or distal extensions at the aortic and iliac ends, respectively. The initial experience with aortoaortic or “tube graft” configurations were unsuccessful due to problems with the distal landing site at the aortic bifurcation and have been abandoned. Indeed, the current strategy is to seat the proximal component of the bifurcated system as close to the lowest renal artery as possible and the distal components as close to the iliac bifurcation as possible to improve immediate seal and fixation and decrease the potential for later aneurysm degeneration at or adjacent to seal sites.

Figure 96-7. The current commercially available infrarenal endografts in the United States are shown: Cook Zenith (A); Medtronic Endurant (B); Trivascular Ovation (C); Gore Excluder (D); Endologix Powerlink (E); Lombard Aorfix (F). These are modular devices consisting of a main body, iliac limbs/extensions and main body extensions. Note the common theme of bilateral iliac limbs and a main body. There are many differences between these endografts, which make them each uniquely suited for some patients. On the top row (A,B,C), the devices all utilize a bare supraceliac stent construct to facilitate fixation. On the lower row (D,E,F), the devices utilize active fixation with hooks (D,F) or anatomic fixation at the aortic bifurcation (E).

Although there is some variability among the commercially available devices in terms of their specific sizes and anatomic constraints, the general anatomic requirements are somewhat similar. The infrarenal abdominal aorta must have a suitable, nonaneurysmal landing zone for the endograft that measures ≥ 10 to 15 mm in length and ≥ 17 to 19 mm, but ≤ 32 mm in diameter (ranges reflect differences between the commercial devices). Furthermore, the proximal neck angle should be ≤ 60 degrees for most devices (≤ 75 to 90 for some newer devices), as measured by the intersection of the centerline of the infrarenal aorta at the landing zone site and the centerline of the aneurysm through the aortic bifurcation. Newer devices do allow for more neck angulation, but the operating surgeon should keep in mind that more infrarenal neck may be required in more severely angulated necks to allow for appropriate seal and fixation of the device. The infrarenal neck should be relatively free of thrombus and calcification to facilitate a seal at the implantation site. It is notable that neck length requirements were initially ≥ 1 cm with the first generation of devices, which was increased to ≥ 1.5 cm with later generations, and now has again been decreased to > 1 cm with some of the most recent devices. Indeed, the longer the infrarenal neck length and, therefore, the longer the device seal zone, the better. The iliac artery should have a suitable landing zone ≥ 20 mm with an associated diameter between 7 and 20 mm to facilitate both anchoring the graft and passing the main device into the aorta. The distal landing zone for the iliac limbs is usually in the common iliac artery although the anatomic constraints with regards to the size of the access vessels and the introduction of the devices are relevant for both the common and external iliac vessels.

The percentage of patients that are anatomically suitable for an endograft remains unresolved and is

likely contingent upon the nature of the individual surgeon/institution practice and the available devices. This percentage of suitable patients has been highly variable with report of 30% in nationwide series,¹²¹ 55% in a regional series,¹²² and 14% to 66% in institutional series.¹²³⁻¹²⁵ Notably, the reasons cited for exclusion include a short infrarenal neck (54%), inadequate iliac vessels (47%), and a wide infrarenal neck (40%).¹²³

A variety of techniques have been described to overcome the anatomic limitations of the endovascular approach thereby extending its feasibility. Indeed, some modification has been described to overcome almost every anatomic contraindication. Stenosis within the access vessels can be overcome by dilation (i.e., balloon angioplasty, serial dilators) or by the use of an open prosthetic conduit or endovascular stent graft conduit.¹²⁶ The open prosthetic conduit is usually anastomosed to the bifurcation of the common iliac artery and then tunneled through the retroperitoneal space below the inguinal ligament. Alternatively, an aorto-uni-iliac endograft can be configured and a femoral–femoral bypass performed. Notably, the patency rates of the femoral–femoral bypass graft in this setting have been reported to be excellent.^{127,128} Aneurysm degeneration of the common iliac artery can be overcome by a variety of techniques including simply using larger-diameter graft limbs, occluding/embolizing the internal iliac artery and seating the iliac limb in the external iliac artery or by bypassing the internal iliac artery (and seating the iliac limb in the external iliac artery). Although relatively simple to perform, internal iliac artery embolization has been associated with a moderate incidence of complications including buttock/thigh claudication (30% to 40%), sexual dysfunction, neurologic deficit/paraplegia, pelvic ischemia, and gluteal compartment syndrome.^{129,130} The claudication improves with time in the majority of patients, but can be quite debilitating, particularly in patients that did not claudicate preoperatively. Many of the other complications, although somewhat rare, are irreversible and can be catastrophic. Because of these concerns, concomitant bilateral internal iliac artery occlusion/embolization should be avoided when possible. Bypass of the internal iliac artery overcomes many of these limitations and has been associated with excellent results in terms of long-term graft patency although the procedure is somewhat challenging and adds significantly to the overall magnitude of the “less-invasive” procedure.¹²⁶ Unfortunately, extending the indications for endovascular repair beyond those recommended by the manufacturers (i.e., instructions for use [IFU]) has been associated with an increase in the incidence of adverse events including decreased survival and a higher need for reintervention.¹³¹ Iliac bifurcation devices are currently commercially available outside the United States and will soon be available inside the United States, and will allow for preservation of internal iliac arteries in select patients with appropriate anatomy.^{132,133}

Consideration of the perioperative and long-term outcomes after EVAR requires introduction of the concepts of endoleak and endotension. Simply, endoleak is the perfusion of the aneurysm sac outside the lumen of the endograft while endotension is the persistent pressurization within the excluded aneurysm sac. Endoleaks have been classified as types 1 through 4 based on the mechanism of the leak (Fig. 96-8). Type 1 leaks originate at either the proximal or distal attachment sites. Type 2 leaks come from branch vessels, such as the lumbar or inferior mesenteric arteries. Type 3 leaks are caused by fabric tears or problems at the graft interfaces of the modular devices, whereas type 4 leaks are usually transient (<24 hours) trans-graft extravasations that result from the porosity of the graft and needle holes. It should be emphasized that the entire concept of an endoleak is predicated on the ability to detect contrast or blood flow outside the lumen of the endograft and is, therefore, contingent on the sensitivity and specificity of the various imaging techniques. The major concern about both endoleaks and endotension is that the pressure transmitted to the aneurysm wall may cause the aneurysm to expand and/or rupture. The clinical significance of the various endoleak types is quite different. Both type 1 and 3 endoleaks are considered major adverse outcomes associated with an increased risk of rupture, and they merit urgent/emergent treatment.¹³⁴ Type 2 endoleaks are generally considered less worrisome in terms of their rupture risk although they are associated with an increased risk for reintervention.¹³⁴ They can generally be followed with serial imaging studies, but merit evaluation/intervention if the aneurysm sac continues to enlarge. Type 4 endoleaks are self-limited and benign. The clinical significance of endotension is likewise unresolved. Indeed, the concept itself is somewhat ambiguous given the limitations of actually measuring the pressure within the aneurysm sac. It should be noted that freedom from endoleak does not necessarily mean freedom from endotension given the observation that aneurysms can continue to enlarge in the absence of an identifiable endoleak.¹³⁵

The *perioperative* complication rates appear to be lower after endovascular repair. As noted above, the randomized, controlled DREAM and EVAR Trials reported a significant decrease in the perioperative

mortality rate (DREAM – 1.2% vs. 4.6%; EVAR Trial – 1.7% vs. 4.7%).^{70,79,109} The EVAR Trial also reported a trend toward a decrease in the combined operative mortality/severe complication rate (9.8% vs. 4.7%, $p = 0.10$). Multiple clinical trials have reported that the overall major complication rates after both endovascular and open repair are approximately 15% although the magnitude of the complications is less for the endovascular approach and primarily includes vascular access complications (e.g., hematoma, femoral artery injury).¹³⁶ These clinical trials have likewise demonstrated that the total hospital length of stay, intensive care unit length of stay, operative blood loss, and time necessary to resume normal activities are all less for the endovascular approach.¹³⁶ In addition, Hua et al.⁷³ reported from the private sector NISQIP database that the perioperative complication rate after endovascular repair was 24%. Interestingly, the impact on sexual function remains unresolved. A survey of the DREAM participants demonstrated that sexual dysfunction was common after both endovascular and open repair, but returned to the baseline state at 3 months for both groups.¹³⁷ In contrast, Xenos et al.¹³⁸ reported significantly less orgasmic and erectile dysfunction after endovascular repair.

Figure 96-8. Type 1 to 4 Endoleaks. Type I and III represent the most dangerous forms of endoleaks, and represent what is essentially an unrepaired aneurysm. **A:** Type I leaks originate at either the proximal (Ia) or distal (Ib) attachment sites. Note the large blush of contrast outside of the graft lumen at the proximal fixation site, demonstrating a type Ia endoleak. **B:** Type 3 endoleaks are caused by fabric tears or problems at the graft interfaces of the modular devices. Note the contrast blush outside of the lumen of the graft at the modular interface. Type II endoleaks generally have a more benign natural history, but can cause aneurysmal growth and rupture. **C:** Demonstrates an inferior mesenteric arteriogram from a catheter (*white arrow*) in the meandering mesenteric artery. Filling of the aneurysm sac through a patent inferior mesenteric artery (*red arrow*) is evident. **D:**

Demonstrates successful embolization of the IMA with coils demonstrated by *black arrows*. Note no further filling of the aneurysm sac.

The long-term results after the EVAR and DREAM Trials have failed to document any significant benefit for the endovascular approach in terms of almost every outcome measure analyzed.^{79,109} Somewhat surprisingly, there was no difference in all-cause mortality at 2 years in the DREAM Trial (survival, open – 89.6%, EVAR – 89.7%) or at 4 years in EVAR (mortality, open – 29%, EVAR – 26%). There were significant differences in terms of aneurysm-related mortality at these time points although the differences were fairly minimal and their relevance suspect. Both the complication rates (EVAR Trial; EVAR – 41%, open – 9%) and costs (EVAR Trial; EVAR – £13,257, open – £9,926) were significantly greater for the endovascular approach while there were negligible differences in the quality of life assessments.^{79,139,140}

The mid-term results from the DREAM and EVAR Trials have been somewhat sobering and longer-term outcomes are necessary to further define the role of the endovascular approach. It is clear that the endovascular approach is not as secure a repair as the traditional, open alternative. The endovascular repair is associated with ongoing rupture risk that likely approaches 1%/yr.^{136,141} Notably, Schermerhorn et al.¹⁹ reported a 1.8% rupture risk among Medicare patients undergoing EVAR between 2001 and 2004. The rupture risk has been associated with poor patient selection, operator error, unrecognized/untreated endoleaks, large aneurysms, and device migration.^{136,142} Interestingly, the mortality rate associated with rupture after endovascular repair may be less than for de novo ruptures.¹⁴³ Approximately 10% to 20% of patients develop an endoleak during the first year after endovascular repair.^{144–146} Admittedly, not all of these require remediation. The excluded aneurysms can continue to grow and, thereby, represent a risk for rupture. This has been correlated not only with the presence of endoleak as noted above, but also with the specific device and the baseline aneurysm size.^{147,148} Some type of structural failure including fabric tears, hook fractures, and suture breakage has been reported for almost every device. Design modifications have been implemented to overcome many of these deficiencies although they represent an ongoing concern that may not be manifest for years. As a consequence of all these potential limitations, reintervention is sometimes necessary either to prevent complications or to treat them. Aneurysm-related reinterventions occurred in 3.7% of patients per year after EVAR from 2001 to 2004 in the Medicare population.¹⁴⁹ The majority of these remedial procedures are minor endovascular procedures, however with a risk of major open procedures of 0.4%/yr.¹⁴¹ In contrast, open aneurysm repair is associated with a less than 1%/yr incidence of aneurysm-related complications that require remedial procedures in long-term follow-up. Graft-related deaths have been reported in 2% of patients at 15 years.¹⁵⁰

The presence of significant comorbidities and advanced age favors the endovascular approach. Although the operative threshold in regards to the aneurysm diameter measurement is the same, the endovascular approach may allow a subset of patients not considered suitable candidates for an open operation to have their aneurysms repaired. Indeed, EVAR has been shown to be feasible in patients with hepatic insufficiency¹⁵¹ and consistently safe in octogenarians.^{152,153} However, a modicum of clinical judgment is necessary, and the concept that AAA repair is a prophylactic operation and that not every patient merits treatment must be kept in mind. The EVAR Trial 2 randomized patients not fit for open repair to expectant management or endovascular repair and demonstrated no difference in aneurysm-related mortality, all cause mortality, or quality of life.¹⁴⁰ Notably, the patients were truly “high risk” with a perioperative mortality rate of 9% and a 4-year mortality rate of almost 40%. Despite the potential nephrotoxicity associated with iodinated contrast, chronic renal insufficiency is not an absolute contraindication to endovascular repair. Strategies to reduce the associated risk can be employed including the administration of acetylcysteine and sodium bicarbonate.^{96,97} Alternatively, the procedure can be performed without contrast altogether by using intravascular ultrasound (IVUS) or CO₂ as the contrast agent. Unfortunately, chronic renal insufficiency is a significant risk factor for adverse outcome after both open and endovascular repair. Furthermore, multiple studies have shown that both approaches are associated with a decrement of renal function.^{154–157} The endovascular approach may be associated with a greater decrement of function postoperatively, but the findings are somewhat equivocal; suprarenal fixation of the endovascular device does not seem to be associated with a greater decrement.¹⁵⁷

The known device-related complications and the uncertainty about the long-term outcome after endovascular repair mandate indefinite surveillance, although the intervals and type of imaging for surveillance remain controversial. Whatever is chosen by the practitioner, patients must agree to

comply with the prescribed protocol and their ability or desire to fulfill these expectations should be factored into the specific choice of procedure. It is important to note that although the incidence of complications declines with the number of negative postoperative CT scans; new endoleaks have been discovered many years after device implantation. Similarly, it is imperative that all surgeons that offer EVAR provide conscientious, long-term follow-up.

The cost comparisons between the open and endovascular approach have been somewhat inconclusive although the endovascular approach is likely more expensive. Clearly, the EVAR-1 and EVAR-2 trials demonstrated that the endovascular approach was more expensive.^{79,140} Although the shorter length of stay and lower incidence of major perioperative complications have resulted in a reduction in some of the hospital costs with EVAR, these benefits have been offset by increases in other hospital-related costs, namely the device cost. Notably, Sternbergh and Money¹⁵⁸ reported that the cost of the device accounted for 52% of the total cost of the endovascular repair and estimated that the costs of open and endovascular repair were \$12,546 and \$19,985, respectively in the AneuRx Phase II clinical trial. Analysis of the hospital costs and reimbursement associated with endovascular repair among 7 medical centers (university hospital – 3, community hospital – 4) demonstrated a net loss of \$2,162.^{158,159} However, others have reported that the contribution to the hospital margin on a daily basis may be superior for endovascular repair given the associated shorter duration of stay that permits higher throughput, fuller overhead amortization, and better use of inpatient beds.¹⁶⁰ It is important to note that most of the analyses have focused on the hospital and device-related costs, but have failed to include the associated professional fees and the costs associated with long-term follow-up and reintervention, which all may be substantial. Importantly, Kim et al.¹⁶¹ reported that reimbursement for endovascular repair does not include long-term surveillance and secondary procedures. Indeed, it has been reported that the overall cost of endovascular repair may be twice that of the open approach.¹³⁶

Despite the various advantages and disadvantages of the approaches outlined above, patients and providers seem to prefer the endovascular approach and these preferences appear to be one of the driving forces for the widespread application of the technique. Indeed, it is uncommon for patients that are candidates for either approach to elect open repair. Notably, Williamson et al.¹⁶² reported that 18% of all patients undergoing open repair would not undergo the procedure again. The potential to perform the endovascular repair completely percutaneously (i.e., no femoral artery exposure) clearly adds to the appeal of the approach.^{163,164} It is interesting to note that these patient preferences may not be sustained. A follow-up study from the DREAM trial reported that patients undergoing endovascular repair had a better quality of life initially, but those undergoing open repair had a better quality at 6 months and beyond.¹³⁷

The proverbial “bottom line” for the open versus endovascular debate remains somewhat unresolved, but the discussion is merely academic at this point. EVAR, when anatomically possible, has essentially become the standard of care in most practices. Notably, the Agency for Health Care Research Quality conducted an evidence-based review published in 2006 and concluded that endovascular repair for aneurysms > 5.5 cm did not improve patient survival or health status relative to open repair despite the fact that the perioperative outcomes were improved.¹⁶⁵ Furthermore, they reported that the endovascular approach was associated with increased cost, complications, need for surveillance and need for remedial procedures. Finally, they concluded that it did not provide a benefit for patients unfit for open repair. Despite these recommendations, the trend toward dominance of EVAR over open repair has increased to a point where many vascular training programs are having difficulty with finding enough open aneurysm cases to sufficiently teach their trainees.¹⁶⁶

OPERATIVE REPAIR

Preoperative Evaluation

The preoperative evaluation of patients undergoing elective AAA repair is similar to that of patients undergoing any major general or vascular surgical procedure. Patients undergoing endovascular repair should likely undergo the same preoperative work-up despite the perception that associated perioperative stresses are less. All patients should receive a complete history and a physical examination, electrocardiogram, and a chest radiograph. Routine laboratory studies, including a complete blood cell count with platelets, serum electrolytes/creatinine, and coagulation studies should be obtained. A specimen should be sent to the blood bank and the appropriate quantity of blood products cross-matched. This number can be determined from the historic operative transfusion

requirements obtained from the blood bank but usually 2 to 4 units of packed red blood cells are sufficient. A thorough peripheral pulse examination should be included in the physical examination and validated with formal ankle–brachial indices. The anesthesiologist should see the patients preoperatively. In addition, patients should be started on an aspirin and a statin (HMG Co-A reductase inhibitors) and consideration made for starting a beta-blocker if they are not already on them. The ACC/AHA Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery recommend that the beta-blockers are “probably recommended” for vascular surgery patients who are at high cardiac risk or those with more than one clinical risk factor (risk factors – CAD, CHF, CVD, DM, CRI).¹⁶⁷ However, much of the data that this recommendation was based upon have been questioned due to reports of unscrupulous academic behavior by the investigators, and many now believe that initiation of beta-blockers before major vascular surgery is unwarranted and potentially harmful.¹⁶⁸

Furthermore, the ACC/AHA Guidelines recommend that patients undergoing vascular surgery should be on a statin. Notably, a recent study demonstrated that statins were associated with a decreased incidence of perioperative mortality and nonfatal myocardial infarction after aneurysm repair.¹⁶⁹ Indeed, all patients with atherosclerotic cardiovascular disease should likely be on aspirin, a statin medication, and an ACE inhibitor long-term as part of the AHA/ACC Guidelines for Preventing Heart Attack and Death in Patients with Atherosclerotic Cardiovascular Disease.¹⁷⁰

All active medical problems, including abnormalities identified during the preoperative evaluation, should be controlled as well as possible before elective aneurysm repair. However, extensive diagnostic testing is probably unnecessary. Routine pulmonary function tests and measurement of arterial blood gases are not indicated, although they may be beneficial in selected patients with advanced chronic obstructive pulmonary disease.¹⁷¹ The presence of chronic obstructive pulmonary disease often complicates postoperative ventilator management, but it is unusual for a patient’s pulmonary disease to be sufficiently severe to preclude operation.¹⁷² Similarly, timed urine collections for creatinine clearance and other assessments of renal function have not proved beneficial despite the dramatic impact of preoperative renal insufficiency on perioperative outcome although it may be beneficial to calculate the estimated glomerular filtration rate.

The appropriate cardiac work-up before AAA repair is evolving and is somewhat institution-dependent. This controversy has been further complicated by the publication of the CARP Trial that examined the role of coronary artery revascularization before major vascular surgery among patients with significant coronary artery disease.¹⁷³ Notably, the study reported that preoperative coronary artery revascularization did not reduce the incidence of either perioperative myocardial infarction or long-term mortality. It is important to emphasize that the overall objective of the preoperative cardiac work-up is to optimize the cardiovascular system and thereby reduce both the perioperative and long-term risk of myocardial infarction and death. Admittedly, the prevalence of coronary artery disease among patients undergoing AAA repair is quite high. Hertz et al.,¹⁷⁴ in a landmark publication, reported that 25% of 1,000 patients undergoing evaluation for peripheral vascular surgery (cerebral vascular occlusive disease, lower extremity arterial occlusive disease, AAA) had severe, surgically correctable lesions detected during cardiac catheterization; 6% had severe, uncorrectable disease, and only 8% had no evidence of disease. Interestingly, the incidence of surgically correctable disease was highest among patients undergoing evaluation for AAA. The most recent edition of the ACC/AHA Guidelines have simplified the preoperative evaluation before elective vascular procedures.^{167,175} Briefly, patients with active cardiac conditions (unstable coronary syndromes, decompensated congestive heart failure, significant arrhythmias, and significant valvular disease) should be seen in consultation by a Cardiologist. Patients with good functional capacity as defined by the ability to generate at least four metabolic equivalents (METs, 4 METs – ability to walk up a flight of stairs) can undergo major vascular procedures without additional testing. Those patients that cannot generate 4 METs and have at least 3 clinical risk factors (see above) should be considered for further cardiac testing if the results will change the clinical management. Notably, there is insufficient evidence to support a reduced cardiac work-up for patients undergoing endovascular repair.¹⁷⁶ It is important to emphasize that although the cardiac risk of endovascular repair may be less, the subset of patients undergoing the procedure are often older and sicker.

All patients should undergo some type of imaging modality as part of their preoperative evaluation to confirm the diagnosis and plan the procedure. Indeed, determining whether a patient is an endovascular candidate and appropriately sizing the device depend on the anatomic measurements obtained at the time of imaging. A CT arteriogram of the chest, abdomen, and pelvis is the optimal imaging study to

visualize the aneurysm and is the only one required in most cases. Abdominal ultrasonography is insufficient as the sole imaging study before aneurysm repair in light of its inability to accurately define the cephalad extent of the aneurysm and the involvement of the iliac vessels.

Open Repair of Intact Abdominal Aortic Aneurysms

Technique

A significant amount of preparation is required in the operating room before making the incision and this preparation needs to be coordinated among the surgical and anesthetic teams for both the open and endovascular approaches. Although the decision about the choice of anesthesia is deferred to the anesthesiologists, inhalation agents and an endotracheal tube are used most frequently. Adjunctive epidural anesthesia may improve postoperative pain control¹⁷⁷ and may be beneficial in patients with severe pulmonary disease.¹⁷⁸ Adequate intravenous access should be established to facilitate resuscitation. Central venous access is usually obtained although not necessary. Electrocardiographic leads, an arterial catheter, and a Foley catheter should be placed for continuous monitoring of the electrocardiogram, arterial pressure, and urine output, respectively. In addition, a nasogastric tube should be inserted. A Swan–Ganz pulmonary artery catheter or a transesophageal echocardiogram probe should be inserted in patients with significant cardiac disease. However, routine use of pulmonary artery catheters in patients undergoing aortic surgery is not recommended and may be associated with a higher rate of intraoperative complications.^{179,180} Peripheral arterial pulses should be interrogated with either palpation or continuous-wave Doppler ultrasound and marked to facilitate confirmation after restoration of lower-extremity perfusion. Strategies to maintain core body temperature should be initiated.^{179,181} Specifically, the room temperature should be increased, warming devices should be attached to all intravenous infusion lines, and either a recirculating alcohol blanket or forced-air blanket should be applied. Bush et al.¹⁸² reported that hypothermia (<34.5°C) during AAA repair was associated with multiple physiologic derangements and adverse outcomes. Of note, this does not pertain to thoracoabdominal aortic surgery where hypothermia has shown some benefits in spinal cord ischemia reduction.¹⁸³

Use of an intraoperative autologous transfusion device should be considered. However, a recent meta-analysis of 5 randomized, controlled trials reported that there is insufficient evidence to recommend its use during vascular surgery including aortic surgery.¹⁸⁴ These devices should likely be used when a significant amount of blood loss is anticipated, such as during suprarenal or thoracoabdominal aortic aneurysm repairs. Furthermore, they can be helpful in patients who object to blood transfusions on religious principles. An extensive operative field from “nipples to toes” should be prepared with the use of topical antimicrobial agents. A first-generation cephalosporin or vancomycin should be administered prior to the incision.

AAAs may be repaired through several different incisions or approaches including midline, retroperitoneal, or transverse (supraumbilical straight, infraumbilical straight, infraumbilical curvilinear, bilateral subcostal). The incisions or approaches must be viewed as complementary since neither is perfect for every clinical scenario. Indeed, surgeons should be familiar with the various approaches and select the optimal one for the clinical setting. The determinants of the incision include the cephalad/caudal extent of the aneurysm, body habitus, presence of prior abdominal incisions, presence of abdominal wall stomas, comorbidities, additional intraoperative pathology, inflammatory aneurysms, renal anomalies, requirements for concomitant procedures, urgency of aortic control, and surgeon preference. The midline approach is preferable for patients with ruptured AAAs because aortic control at the level of the diaphragm can be obtained rapidly. The bilateral subcostal approach provides the best exposure and is the incision of choice for obese patients, those with extensive iliac artery aneurysms, those patients requiring concomitant renal artery revascularization, and those patients with juxtarenal aneurysms that require suprarenal aortic control. The retroperitoneal approach is optimal for patients with multiple previous abdominal incisions (“hostile abdomen”), abdominal wall stomas, suprarenal aneurysms, inflammatory aneurysms, and horseshoe kidneys. However, the retroperitoneal approach is limited by the inability to assess the intraperitoneal structures and the limited access to the right renal artery and right iliac vessels. It was previously contended that the retroperitoneal approach posed less of a physiologic insult than the transperitoneal approach and, therefore, was ideal for patients with advanced pulmonary or cardiac disease. However, this has not been supported by a prospective, randomized trial.¹⁸⁵ A detailed description of the retroperitoneal approach is beyond the context of this chapter, but is available in most standard vascular surgical texts.

The sequence of steps used to repair an intact, infrarenal AAA after a bilateral subcostal incision can

be summarized (Fig. 96-9). The abdomen is explored after the peritoneal cavity is entered, and both the gallbladder and colon carefully examined. The lower abdominal wall flap is immobilized to either the drapes or the pubic towel with the use of penetrating towel clips. The small bowel is manually retracted laterally to the right, and the duodenum is mobilized by incising the ligament of Treitz. The inferior mesenteric vein may be suture-ligated at this juncture to facilitate exposure. The tissue adjacent to the inferior mesenteric vein should be palpated to rule out a large, meandering mesenteric artery. This artery is an important visceral collateral and should be preserved. The retroperitoneum over the aorta is incised with the electrocautery, and the left renal vein is exposed. Self-retaining retractors (e.g., Bookwalter, Omni retractors) are then placed to facilitate further exposure. The small bowel is placed in a bowel bag, eviscerated, and retracted laterally to the right with the aid of malleable self-retaining retractors. The transverse colon and superior abdominal wall flap are retracted cephalad while the lower abdominal wall is further retracted caudal. The aorta immediately inferior to the renal arteries is exposed and both renal arteries visualized. The infrarenal aorta at this location is dissected circumferentially to facilitate placement of a transverse aortic clamp. However, this step may be omitted if a vertical clamp is used. It is important to identify the course of the renal vein and any venous anomalies on the preoperative CT scan to prevent inadvertently injuring these structures at this stage of the procedure. In the presence of a retroaortic renal vein or circumaortic collar, the aortic neck should not be dissected circumferentially and vascular control should be obtained with a vertical clamp. The retroperitoneum over the aorta is then incised further caudally and the incision extended along the course of the right common iliac artery. The extent of the caudal dissection depends on the anatomic configuration of the aneurysm. If the aneurysm extends to the aortic bifurcation, it is sufficient to dissect only the common iliac arteries provided a suitable site for clamp application is identified. If the aneurysm extends to the distal common iliac arteries, both the internal and external iliac vessels should be dissected free. This may be facilitated on the left side by mobilizing the sigmoid colon along its peritoneal reflection and reflecting it medially. The inferior mesenteric artery is then dissected free and vascular control obtained with a vessel loop. Patients are administered 100 units/kg of intravenous heparin, and the activated clotting time is confirmed to be twice the baseline value. Supplemental doses of heparin are administered throughout the procedure as dictated by the activated clotting time. Interestingly, a recent randomized, controlled trial reported that heparin does not reduce thrombotic events or increase bleeding during aneurysm repair, but is associated with a significant reduction in myocardial events.¹⁸⁶

Figure 96-9. Steps involved in the standard repair of an infrarenal abdominal aortic aneurysm extending into the proximal common iliac arteries. **A:** The proximal duodenum is mobilized and the retroperitoneum overlying the aorta incised. The infrarenal aorta immediately below the renal vein is dissected. The iliac bifurcations are exposed, and vascular clamps are applied to the infrarenal aorta and distal common iliac arteries after adequate heparinization. A longitudinal arteriotomy is extended from the infrarenal aorta onto the right common iliac artery. **B:** Back bleeding from the lumbar arteries is controlled with “figure-of-eight” sutures. The proximal anastomosis is performed in an end-to-end configuration below the renal arteries. The distal anastomoses are performed at the common iliac bifurcation beyond the aneurysmal segments. The left limb of the graft is tunneled through the intact left common iliac aneurysm shell. **C:** The residual aneurysm shell is closed over the prosthetic graft, and the retroperitoneum is reapproximated to prevent erosion of the graft into the overlying bowel.

During the time required for adequate mixing of the heparin, the availability of the necessary equipment is reviewed and confirmed with the operating room personnel. The appropriately sized prosthetic graft is selected. The graft diameter is sized according to the infrarenal aortic neck by visual inspection or with the calibrated graft rulers (i.e., “sizers”). The general “rule of thumb” is that the smaller graft should be selected when the aorta is between two graft sizes because the aorta always appears smaller after it is transected and redundant graft material at the proximal anastomosis is more difficult to correct than the opposite problem. A variety of vascular prostheses are available. Despite the contentions of the various manufacturers, there is no clear advantage for an individual graft and the choice should be determined by surgeon preference as dictated by ease of handling, cost, and availability. The distal vascular clamps are applied to the external, internal, or common iliac vessels depending on the extent of the aneurysm and the character of the vessels. Occasionally, the iliac vessels are so calcified that they cannot be safely occluded with a clamp. Vascular control may be obtained intraluminally in this setting with the use of a balloon thromboembolism catheter after the aneurysm has been incised. The proximal aortic clamp is applied in sequence after the distal clamps. The clamp is applied immediately below the renal arteries to facilitate an anastomosis to the proximal infrarenal aorta. The length of the infrarenal aorta should be sufficient to permit a safe anastomosis. However, a long infrarenal cuff should be avoided because it may become aneurysmal over time. Either a vertical or horizontal aortic clamp may be used. The aorta is then incised longitudinally, and the incision is extended to the distal aorta and into the iliac arteries if the distal anastomosis will be to the iliac vessels. Attempts should be made to preserve the autonomic nerves overlying the distal aorta and proximal left common iliac artery in potent men. This can usually be achieved by incising the left common iliac artery transversely beyond the aneurysmal portion and tunneling the limb of the graft through the residual shell. The intraluminal thrombus and debris are removed from within the aorta, and all back bleeding from the lumbar arteries is controlled with suture ligatures. The atheromatous debris within the aorta has been reported to be culture-positive in approximately 25% of cases although this has not been associated with long-term graft infections.^{187,188} The infrarenal aorta at the level of the planned proximal anastomosis may be completely transected, or the back wall may be left intact. Completely transecting the aorta makes the proximal anastomoses slightly easier although leaving the back wall intact reinforces the anastomosis and provides the equivalent of an autogenous pledget. The proximal anastomosis is performed in an end–end configuration with a running 3-0 cardiovascular suture. All leaks in the suture line are repaired with similar 4-0 or 5-0 sutures and felt pledgets as necessary. The distal anastomosis or anastomoses are performed to the aortic bifurcation, common iliac arteries, or iliac bifurcation as dictated by the anatomy of the aneurysm. Occasionally, patients with extensive concomitant iliac disease may require anastomoses at the femoral arteries. A 3-0 cardiovascular suture is used for anastomoses at the aortic bifurcation, and a similar 4-0 suture is used for the common iliac arteries. All anastomoses are flushed to remove any intraluminal debris before flow is restored. Blood flow is restored to the pelvis and lower extremities in sequence. Attempts should be made to flush initially into the internal iliac circulation to prevent embolization to the lower extremities. This can be facilitated by manually compressing the common femoral arteries for tube graft configurations. The lower torso should be reperfused gradually (i.e., one vessel at a time and one extremity at a time) to prevent hypotension. This process requires significant communication and coordination between the surgical and anesthetic teams. It is imperative that the patient is resuscitated prior to reperfusion and it is frequently necessary to delay this process to allow the anesthesiologists to achieve this objective. Reperfusion of the ischemic tissue causes the release of acid, potassium, and a variety of inflammatory mediators and reactive oxygen species into the systemic circulation, all of which are potentially detrimental.

The inferior mesenteric artery may be reimplanted into either the body of the graft or the left limb if it is patent. Seeger et al.¹⁸⁹ reported that routine reimplantation of the inferior mesenteric artery resulted in decreased rates of colonic infarction and death after aortic reconstruction. However, a more recent randomized, controlled trial demonstrated no benefit in terms of morbidity or mortality although the authors suggested it may be beneficial for older patients and those with increased blood loss.¹⁹⁰ The colon and lower extremities should be interrogated with the Doppler ultrasound after reperfusion, and the heparin reversed with intravenous protamine sulfate after confirmation of adequate signals. The protamine dose is estimated based on the effectiveness of protamine (1 mg of protamine per 100 units of heparin), the initial dose of heparin, the current activated clotting time, and the elapsed time from the administration of heparin. The protamine should be administered slowly to prevent any untoward hemodynamic events.¹⁹¹ Notably, a recent randomized, controlled trial reported that protamine

effectively reverses the heparin effect, but provides no clinical benefit during peripheral vascular surgery, including aneurysm repair.¹⁹² The shell of the aneurysm and the overlying retroperitoneum are both closed with absorbable suture to provide a biologic tissue layer between the graft and the viscera. The retractors are then removed, the viscera are returned to their anatomic positions, the nasogastric tube is confirmed to be in the antrum, and the abdominal wall fascia is closed with standard technique. Notably, patients undergoing aortic reconstruction for aneurysmal disease have been reported to have a higher incidence of abdominal wall hernias than those undergoing reconstruction for occlusive disease.^{193–195}

The configuration of the aortic reconstruction (aorto-aortic, aortoiliac, aortofemoral) depends on the extent of aneurysmal involvement and the degree of occlusive disease. Aneurysmal involvement of the common iliac vessels should be considered an extension of the aortic process and treated appropriately. Specifically, common iliac arteries larger than 2 cm should be considered aneurysmal and replaced. The entire common iliac artery must usually be replaced although it is possible to replace only the proximal segment if the aneurysmal involvement is isolated. Conversely, common iliac arteries smaller than 2 cm have a relatively benign natural history and do not need to be replaced since only a small percentage become aneurysmal and require treatment.^{196,197} Despite the fact that a patient may be a candidate for an aortic tube graft, it is often easier to perform an aorto-bi-iliac graft because the terminal aorta is often very calcified. Aorto-bi-femoral bypass grafts should be reserved for the small subset of patients who truly have concomitant aneurysms and severe occlusive disease since the risks of wound complications and graft infections are greater. Indeed, the risk for graft infections is less than 0.5% for aorto-bi-iliac grafts, but approximately 2% for aorto-bi-femoral grafts.^{196–198} It is important to remember the original indication for the procedure and choose the appropriate aortic reconstruction (aorto-bi-iliac bypass for aortoiliac aneurysm, aorto-bi-femoral bypass for aortoiliac occlusive disease). Admittedly, there is a role for aorto-bi-femoral reconstructions in patients with aneurysm disease, and it is futile to attempt an aorto-bi-iliac reconstruction in patients with severe external iliac artery disease.

The postoperative care after open repair is fairly routine and predictable for the majority of patients. Patients are transferred directly from the operating room to the intensive care unit although selective use of the intensive care unit may be appropriate.¹⁹⁹ Most of the patients are extubated in the operating room or shortly after arrival in the intensive care unit. The intensive care unit length of stay is usually 1 to 2 days, and the median total length of stay is 8 days.³⁴ Patients are encouraged to get out of bed and begin ambulating in the early postoperative period (i.e., 24 to 48 hours). Preoperative prophylactic antibiotics are continued for a total of 24 hours. Nasogastric decompression is continued until bowel function returns. Oral feedings are initiated after removal of the nasogastric tube and advanced quickly to solids. Patients are discharged when they are ambulatory, can tolerate a regular diet, have normal bowel function, and are sufficiently able to care for themselves. A subset of people requires transfer to rehabilitation or extended care facility. Patients are usually seen in the clinic 2 weeks after discharge and then at 6 months thereafter. Additional clinic appointments may be necessary as dictated by any ongoing medical problems. Patients are not allowed to drive until their incisional pain has resolved and they have stopped taking pain medications. Furthermore, patients are discouraged from lifting heavy objects for the first 6 to 8 weeks to reduce the incidence of incisional hernias.

Complications and Outcome

Open repair of intact AAAs is associated with significant mortality and morbidity.^{34,200,201} The attendant mortality rates have been discussed extensively in the preceding sections entitled Principles of Management and Choice of Open or Endovascular Repair. Briefly, the contemporary mortality rate across the country has consistently been <5%.^{72–74} The overall morbidity rate remains less clear, although the specific complications have been well defined. Huber et al.³⁴ reported that 33% of all patients undergoing repair of intact AAAs across the United States develop some type of perioperative complication as defined by the ICD-9 postoperative complication codes. Similarly, Hua et al.⁷³ reported from the National Surgical Quality Improvement Program – Private Sector that the overall incidence of 30-day morbidity after open repair was 35%.

Intraoperative complications can result from injury to the intra-abdominal structures during dissection although these technical complications are not specific to the aneurysm repair. The small bowel, colon, ureter, and major venous structures (inferior vena cava, iliac veins, left renal vein) are particularly susceptible. Iatrogenic bowel injury at the time of AAA repair is particularly problematic due to the potential to infect the prosthetic graft. If the colon is injured before the aneurysm repair, the defect in the colon should be fixed and the aneurysm repair should be aborted. If the small bowel is injured

before the aneurysm repair, the same course should likely be followed although this decision requires a modicum of clinical judgment. The infectious concerns must be balanced by the fact that the small bowel contents are sterile, a second procedure will be required to repair the aneurysm, and the small risk of aneurysm rupture during the intervening delay. Injury to the bowel during or after implantation of the aortic graft should be treated with repair of the defect, extensive irrigation, and prolonged antibiotics. Admittedly, these approaches are very conservative and it is noteworthy that multiple clinical series have attested to the safety of simultaneous aortic and gastrointestinal/urologic procedures.^{202–205} The ureter is susceptible to injury at the point where it crosses over the iliac bifurcation. Injury can be avoided by a heightened awareness of this anatomic location and dissection in the tissue plane immediately on top of the common iliac vessels. Inadvertent venous injury can be associated with significant bleeding. This can usually be controlled by direct pressure using sponge sticks and suture repair. The left renal vein may be transected if necessary. It should be transected near its juncture with the vena cava, and the gonadal, adrenal, and lumbar branches should be preserved to maintain venous outflow from the kidney. Although somewhat inelegant, division of the left renal vein does not appear to affect renal function after AAA repair.²⁰⁶ Transecting the common iliac artery or infrarenal aorta may facilitate exposure of the common iliac or retroaortic renal veins, respectively.

Excessive intraoperative bleeding may be encountered occasionally. Routine elective aneurysm repairs are usually associated with moderate intraoperative blood loss with a mean transfusion requirement of 1 to 2 units of packed red blood cells. Excessive bleeding may be caused by either the surgical trauma or coagulopathy. Reversal of the heparin with protamine may help correct the coagulopathic bleeding. Patients with significant bleeding and platelet counts below 50,000/mL should receive a platelet transfusion, and it should be considered for coagulopathic bleeding and counts below 100,000/mL or for those on preoperative clopidogrel or other equivalent anti-platelet medications. Transfusions of fresh frozen plasma are indicated for both patients with either significant bleeding in conjunction with prolonged coagulation studies (>1.5 times control value) and those with coagulopathic bleeding. Massive bleeding, defined as more than 100% of the blood volume, may induce a dilutional coagulopathy with prolongation of the coagulation studies. Additional blood products should be set up in the blood bank in the event of significant bleeding. This may require an additional blood bank specimen. Intraoperative autologous transfusion devices should also be considered if not already in use.

Ischemia of the lower extremities has been reported to occur approximately 3% of the time after open repair.²⁰¹ The causes are multiple and include distal embolization, thrombosis, clamp injury, and technical errors. The lumen of the aneurysm is frequently filled with both thrombus and atheromatous debris that may serve as a source for both macro- and microembolization. The macroemboli usually lodge at the bifurcations of the major vessels; the microemboli usually lodge in the digital vessels and, unfortunately, are not amenable to mechanical extraction. Thrombosis may result from inadequate heparinization, hypercoagulable conditions, or poor arterial runoff. The technical conduct of the operation outlined above is designed to minimize the ischemic complications. The specific maneuvers include anticoagulation, selection of a suitable site for distal clamp application and anastomosis, intraluminal control of severely calcified vessels, flushing of the vessels before clamp removal, and sequential removal of the vascular clamps. Further intervention is mandatory if the lower extremities are found to be ischemic. Anastomotic defects should be corrected. This may simply require disassembling and redoing the anastomosis, but often requires placing the anastomosis further distal on the outflow artery. If no problems are identified at the distal anastomosis, the femoral vessels should be explored and an intraluminal thrombus removed with a balloon embolectomy catheter. A transverse arteriotomy may be created in the common femoral artery if it is anticipated that only a thrombectomy will be required; a longitudinal incision should be created if a bypass (inflow or outflow) procedure is anticipated. The transverse arteriotomy can simply be closed with interrupted sutures without narrowing the lumen in the event that an additional bypass procedure is not necessary, whereas the longitudinal arteriotomy requires a patch closure. A bypass from the aortic graft to the femoral vessels is required if adequate inflow cannot be restored with thrombectomy alone. The popliteal artery below the knee should be explored and a thrombectomy performed if the extremity is still ischemic. This may be facilitated by creating a longitudinal arteriotomy on the below knee popliteal artery that extends to the tibioperoneal trunk. This allows the passage of the balloon embolectomy catheter into all three tibial vessels under direct vision. A below knee popliteal or tibial artery bypass is required if adequate perfusion to the distal extremity is not restored after patch closure of the popliteal arteriotomy. Predictably, a complex lower-extremity revascularization in conjunction with an aortic reconstruction is

associated with a significant degree of morbidity and dramatically increases the mortality rate.²⁰⁷ The decision to proceed with an infrainguinal bypass depends on the status of the extremity and requires some clinical judgment. Aborting the procedure and allowing for a period of observation and re-warming is appropriate when popliteal Doppler signals are detected and the foot is cool yet not severely ischemic. Reoperation and definitive treatment may be necessary in the early postoperative period unless marked improvement is noted.

Many of the systemic complications that follow open aneurysm repair are not surprising, given the magnitude of the operation and the age/comorbidities of the patients. Cardiac complications (ischemia, infarction, arrhythmias, congestive heart failure) occur in up to 25%^{200,201,208} and are the leading cause of death after open aneurysm repair in many series. Pulmonary complications (pneumonia, ventilator dependence > 48 hours, acute respiratory distress syndrome) are also quite common and approximately 10% of the patients require prolonged ventilation.^{200,201} Deterioration of renal function, defined by an increase in serum creatinine or blood urea nitrogen, occurs in approximately 5% of cases although acute renal failure requiring dialysis is rare (i.e., <1%).²⁰¹ The potential causes of renal insufficiency in the perioperative period are numerous and include contrast nephrotoxicity, hypovolemia, atheroembolization, and the inflammatory response from the lower torso ischemia/reperfusion injury. Postoperative bleeding requiring reexploration, intra-abdominal abscess, and abdominal wound complications are all relatively infrequent complications and are associated with all major intra-abdominal procedures.

Ischemic colitis has been reported to occur in approximately 2% to 13% of cases after open aneurysm repair.^{209,210} The reported incidence depends on the diagnostic algorithm and modality (routine sigmoidoscopy vs. selective sigmoidoscopy) and is dramatically increased after ruptured aneurysm repair. Indeed, the incidence of colonic ischemia after ruptured aneurysm repair in patients undergoing routine colonoscopy is approximately 25% to 40%.^{209,211} Multivariable analysis of patients undergoing both open and endovascular repair demonstrated that the duration of the procedure and preoperative renal insufficiency were also predictors of colon ischemia.²¹⁰ The sigmoid colon is affected most frequently although all the sections of the colon may be involved. The ischemia may result from inadequate resuscitation, disruption of collaterals, and/or failure to revascularize a hemodynamically significant inferior mesenteric artery. Patients usually present with bloody diarrhea in the early postoperative period. However, the diagnosis should be considered in the absence of bloody diarrhea in patients with thrombocytopenia, multiple-organ dysfunction, increasing abdominal pain/peritonitis, and generalized “failure to thrive.” The diagnosis may be confirmed by endoscopy. Although sigmoidoscopy is used most frequently, a complete colonoscopy is likely optimal due to the potential involvement of the other colon segments. Treatment depends on the endoscopic findings and clinical setting. The endoscopic findings range from mucosal ischemia to transmural necrosis. Unfortunately, it is often difficult to differentiate diffuse mucosal ischemia from transmural necrosis. In the absence of peritonitis, patients with mucosal ischemia alone should be treated with bowel rest, broad-spectrum antibiotics, total parenteral nutrition, and serial endoscopic examinations. Many of these lesions resolve spontaneously without long-term sequelae although colonic strictures may develop in a subset of patients. Patients with transmural colonic necrosis should undergo laparotomy with resection of the involved segment, a proximal diverting colostomy, and a distal Hartmann’s pouch. After laparotomy, they should be maintained on broad-spectrum antibiotics and parenteral nutrition. The reported mortality rate in patients with transmural necrosis may range up to 85%.^{209,210} Maintaining antegrade flow through the internal iliac vessels, routinely implanting the inferior mesenteric artery, and avoiding disruption of the colonic collateral circulation may reduce the incidence of this adverse outcome.

Several other gastrointestinal complications are common after standard infrarenal AAA repair.²¹² A postoperative ileus develops in essentially all patients with bowel function usually returning within 3 to 5 days. An ileus may persist beyond this time period in a subset of patients although no additional therapy is usually required. Nasogastric decompression should be continued, narcotics minimized, electrolytes normalized, and ambulation encouraged. Either calculous or acalculous cholecystitis may develop after aneurysm repair. The mortality rates reported historically for postoperative cholecystitis were significant²¹³ and served as the catalyst for simultaneous cholecystectomy and aneurysm repair. Although this approach has been found to be safe and not associated with an increased risk for graft infections, it is usually reserved for patients with small stones or evidence of chronic cholecystitis. Pancreatitis may develop after AAA repair although the incidence is surprisingly low in light of the obligatory manipulation of the pancreas during repair. The treatment of pancreatitis in this setting is conservative and includes bowel rest, parenteral nutrition, and serial imaging.

Sexual dysfunction is quite common after both open and EVAR as noted above. Erectile and/or orgasmic dysfunction has been reported to occur in 5% to 18% of men undergoing aortoiliac reconstruction.²¹⁴ The responsible mechanisms include interruption of the pelvic perfusion and injury to the autonomic nerves that overlie the distal aorta/proximal common iliac arteries. Injury to these autonomic nerves disrupts the internal sphincter mechanism of the bladder and results in retrograde ejaculation. Care should be exercised during aneurysm repair to maintain pelvic perfusion and avoid nerve injury to prevent these untoward complications. It is imperative that these potential complications be discussed with patients preoperatively.

Paraplegia after open infrarenal AAA repair occurs with an incidence of 0.25%.²¹⁵ The potential mechanisms for this devastating complication include embolization, thrombosis of the spinal artery, and disruption of the spinal blood supply. Paraplegia after aneurysm repair is usually an irreversible injury. Maintaining adequate antegrade pelvic perfusion through the internal iliac arteries may minimize this complication.

The long-term outcome after open repair is generally favorable. Long-term survival is improved after aneurysm repair, although it falls short of the age-matched controls with survival rates of approximately 90%, 65%, and 40% at 1, 5, and 10 years.^{2,13,216} Cardiovascular causes account for the leading cause of death.²¹⁷ This underscores the importance of long-term medical follow-up and the AHA/ACC Guidelines for preventing myocardial infarction and death.^{170,217} Prosthetic aortic grafts are associated with long-term complications with a reported incidence of approximately 10% to 15% at 15 years.^{136,218,219} Notably, bifurcated grafts are associated with a higher incidence of complications (13%) than tube grafts (5%).¹⁹⁶ The long-term graft-related complications include infection, aortoenteric fistula, thrombosis, and pseudoaneurysm formation. Additional aneurysms of a sufficient size to merit intervention develop in approximately 5% to 15% of patients in either the iliac vessels or the aorta above the prosthetic graft.^{196,197} It is recommended that patients undergo CT of the complete aorta and iliac vessels 3 to 5 years postoperatively to screen for graft complications and additional aneurysms.²²⁰

Endovascular Repair of Intact Abdominal Aortic Aneurysms

Technique

The preoperative evaluation and preparation before endovascular AAA repair is significantly more complicated than for the open approach. The various imaging studies must be reviewed before it can be determined whether the endovascular approach is even feasible. Appropriate measurements must be taken and the necessary devices/components selected. An operative plan must be generated including specific modifications of the standard approach to overcome the patient's anatomic limitations and, thereby, extend the feasibility of the technique. Indeed, “preoperative planning, preoperative planning, and preoperative planning” have facetiously been identified as the three most important components of a successful repair.

A variety of imaging techniques (i.e., CT, catheter-based arteriography) been employed to determine the feasibility of an aneurysm for endovascular repair and select the appropriate devices/components. However, CT arteriography with 3D reconstructions has emerged as the optimal approach. It is important to emphasize that no imaging technique is perfect and, consequently, a certain degree of flexibility is necessary for the operative plan. Measurements obtained from the 3D CT tend to overestimate the actual renal artery–internal iliac artery length assumed by the graft when deployed in vivo. Similar sizing limitations are associated with the catheter-based arteriography techniques and these have been attributed to the course of the catheter, the presence of intraluminal thrombus, and the conformational changes in the aorta that result from the stiff guide wires and/or the device itself.

The various devices/components should be selected using the underlying principles that the main body of the device should sit as close to the orifices of the renal arteries as possible while the iliac limbs should extend to the orifices of the internal iliac arteries. This methodology not only provides exclusion of abnormal tissue, but also extends the length of seal and fixation of the endograft, and may provide additional column strength for grafts requiring this for durability. Furthermore, the manufacturers' recommendations for sizing and device selection should be followed, although many publications have demonstrated reasonable durability of some grafts even when used outside of the “IFU”.²²¹ Grafts seated well below the orifices of the renal arteries have been associated with proximal migration²²² while oversizing the graft diameter beyond that recommended has been associated with both graft migration and aneurysm reexpansion.²²³ The endograft is sized according to the anatomic configuration of the aneurysm and adjacent arteries, and this must be performed in advance of the procedure to ensure that the appropriate devices are available. The diameter and length of the infrarenal cuff,

aneurysm, and iliac vessels must be measured precisely. In addition, the distance from the lowest renal artery to the aortic bifurcation and both renal bifurcations needs to be determined. The diameter of the proximal graft is chosen to oversize the aortic cuff and iliac arteries by approximately 10% to 20%. Additional devices should be ordered for each case including two iliac limbs and an aortic extension cuff to allow for any discrepancy between the preoperative plan and the actual course of the graft in vivo. Each endograft procedure and device configuration is “custom fit” for an individual patient. Work sheets are available from the manufacturers to confirm the suitability of an aneurysm for endovascular repair and to aid in the selection of an appropriate device. Technical assistance is available from the various manufacturers to facilitate every step of the process from initial assessment to component selection to deployment. Furthermore, physicians typically are required to complete a training course comprised of sizing exercises and monitored deployments.

The choice of the specific endovascular device is contingent upon the anatomic constraints of the aneurysm, device associated outcome, and surgeon preference. There are specific differences between the various grafts that lend themselves to different clinical scenarios. The specific considerations include neck diameter, neck length/angulation, renal–internal iliac artery distance, common iliac artery diameter, and access vessel diameter. For example, a graft with suprarenal fixation may be more suitable for a shorter neck while a lower profile system (i.e., smaller outer diameter of the delivery sheath) may be most appropriate for patients with smaller access vessels (i.e., common femoral and external iliac arteries). Despite the initial concerns about compromising renal function, suprarenal fixation has been consistently shown to be safe.^{157,224} Deployment of the various endografts is reasonably involved from a technical standpoint; thus, it is not particularly surprising that most surgeons elect to concentrate on one or two devices. All available endografts currently on the market can treat a patient with “straightforward” anatomy, and a high level of comfort with a limited number of devices has some benefit. However, a working knowledge and comfort level with all devices on the market is advised given the benefits that each graft may have over the others in certain scenarios. This allows use of a graft that best meets the individual patient’s needs.

The need for adjunctive procedures to facilitate the endovascular repair is usually determined by the preoperative imaging and should be factored into the overall plan. The major concerns include stenotic access vessels and the absence of a suitable common iliac artery landing zone due to aneurysm enlargement. The remedial procedures for small access vessels or significant occlusive disease include serial dilation or a retroperitoneal prosthetic iliac conduit. Repeated attempts to pass the devices sheaths through a diseased native vessel should be avoided and can result in vessel rupture at the common iliac bifurcation. Aneurysm degeneration of the common iliac artery can be overcome by seating the iliac limb in the external iliac artery. This necessitates either embolizing or bypassing the ipsilateral internal iliac artery. Alternatively, the iliac limb of the endograft can simply occlude the internal iliac artery flush provided the iliac bifurcation is sufficiently tapered.²²⁵ Several reports have documented that accessory renal arteries may be covered at the time of the endograft with little clinical sequelae, although the individual patient’s baseline renal function certainly must be taken into account.

The intraoperative preparation for endovascular repair is similar to that for the open approach although there are several significant differences. The appropriate imaging equipment is mandatory. Ideally, this would entail a complete endovascular suite with a fixed fluoroscopic unit although a portable unit with the appropriate vascular software and an imaging table is adequate. General endotracheal anesthesia, local and regional anesthesia can all be used for endovascular repair, depending on the individual patient, the clinical scenario, the planned length/complexity of the procedure, and the comfort level of the surgeon and anesthesiologist. Indeed, the endovascular approach is well suited for these less invasive alternatives particularly considering the feasibility of a completely percutaneous approach. For a straightforward endovascular repair, intraoperative autologous transfusion devices and a nasogastric tube are unnecessary. It is currently quite rare to convert to an open repair at the time of the initial implantation despite the early experience that reported a rate of up to 5%.^{75,76,78,226} However, it should be emphasized that EVAR is a surgical procedure and most would agree that the procedure should be performed in an operating room with strict aseptic technique.

Although the technique for implanting the various endografts is somewhat specific to the individual device, the basic steps for deploying a “generic” modular bifurcated device using an open femoral artery exposure is illustrated (Fig. 96-10).

Figure 96-10. General steps involved in the endovascular repair of an abdominal aortic aneurysm. The common femoral arteries are exposed bilaterally (alternatively, and more commonly, percutaneous access is achieved and “preclose” sutures are placed) and stiff wires are introduced into the thoracic aorta under fluoroscopic guidance. An appropriate sized large diameter introducer sheath is inserted over the stiff wire into the body of the aneurysm at approximately the L3 vertebral space on the side contralateral to the one chosen for the main device. If the device is contained within its own deployment system, a sheath may not be required. **A:** The main body delivery catheter is introduced over the stiff wire through the ipsilateral groin and the upper limit of the main body positioned between the L1 and L2 vertebral bodies. An aortogram is obtained and the location of the renal arteries identified. The location of the renal arteries is marked on the imaging screen and the position of the main body finely adjusted. **B, C:** The main body is deployed exposing the opening of the contralateral docking limb. The contralateral docking limb is cannulated and a stiff wire advanced into the thoracic aorta. After confirming successful cannulation of the docking limb, deployment of the contralateral limb is deployed after marking the origin of the hypogastric artery. The hypogastric origin can be identified by using intravascular ultrasound or by obtaining a retrograde arteriogram through the sheath in the opposite oblique projection to identify the orifice of the internal iliac artery. **D,E,F:** The location of the orifice is marked on the imaging screen the contralateral limb is then introduced over the stiff wire, appropriately positioned, and deployed. A compliant aortic occlusion balloon is advanced over the stiff wire and inflated in the region of the infrarenal neck to mold the proximal and distal attachment sites, and used to ensure the overlapping devices are well sealed.

Percutaneous access to the common femoral arteries has become standard for many physicians using a “preclose” methodology that involves placing a suture-based closure system that is deployed prior to delivery of the device and closed at the conclusion of the procedure.^{163,164} If the surgeon is uncomfortable with that approach, or the femoral artery anatomy precludes use of closure devices, an open exposure works well and can be done through transverse, longitudinal or oblique incisions, depending on the clinical scenario. Briefly, the common femoral arteries are exposed and an umbilical tape or vessel loop is wrapped circumferentially around the vessels at the level of the inguinal ligament to facilitate vascular control. Approximately 2 cm of the common femoral artery is dissected free. It is not usually necessary to dissect the superficial femoral and profunda femoris branches. While the dissection is being performed, the various device components are prepared on the back table by the surgical technologist. A purse string suture using a 4-0 or 5-0 cardiovascular suture can be placed on the anterior aspect of the common femoral artery and left untied until the completion of the procedure. The various catheters/sheaths may be introduced through the center of the purse string, thereby, facilitating a rapid/simple closure of the artery at the completion of the procedure. The common femoral artery on the side chosen to introduce the main body of the device (ipsilateral groin) is punctured using an angiographic needle and a 0.035-in standard working wire (e.g., Bentsen) is passed into the abdominal aorta using fluoroscopic guidance. A 5-Fr introducer sheath is advanced over the guidewire using a Seldinger technique and vessel entry is confirmed by manual contrast injection. The working wire is further advanced into the thoracic aorta and exchanged for a longer 0.035-in stiffened guidewire (e.g.,

Lunderquist, Meier) using a catheter. Attention is then directed to the contralateral groin and in a similar manner a guidewire is advanced into the aorta and an appropriate sized introducer sheath is inserted over the guidewire into the body of the aneurysm at approximately the L3 vertebral space. An angiographic catheter is advanced to the L1 vertebral body through the contralateral sheath and the catheter connected to the power injector. The patient is then anticoagulated with heparin using a standard protocol (100 units/kg) and therapeutic anticoagulation (ACT twice baseline) is maintained throughout the procedure. The main body delivery catheter is introduced over the stiff wire through the ipsilateral groin and the upper limit of the main body positioned between the L1–L2 vertebral bodies. Devices that do not have an integral sheath as part of their delivery system require an 18- to 22-Fr sheath to be inserted prior to introduction of the actual delivery catheter. Radiopaque markers on the graft facilitate the positioning and orientation of the main body.

As imaging has improved, multiple techniques allow for determining the proper location of endograft deployment. This may involve the use of IVUS or 3D overlay imaging, both of which can decrease the use of contrast and the radiation exposure to both the patient and practitioner. In the absence of these advanced imaging techniques, an aortogram can be obtained after delivery of the endograft to the location of the renal arteries and the renal arteries marked for device deployment. In this scenario, the flat panel or image intensifier should be adjusted to optimize visualization of the infrarenal neck. A 5- to 10-degree craniocaudal angulation is usually sufficient to account for the anterior angulation of the infrarenal neck caused by the natural lumbar lordosis of the spine and the posterior bulging of the aneurysm sac. However, the optimal angulation or orientation may be estimated based upon the preoperative 3D CT images. The location of the renal arteries is marked on the imaging screen and the position of the main body adjusted. The main body is now deployed exposing the opening of the contralateral docking limb. Using a combination of a hydrophilic wire and a curved catheter, the contralateral docking limb is cannulated. This can be challenging at times and requires a modest degree of catheter skills. Various maneuvers including different fluoroscopic projections, different shaped catheters, and proper orientation of the contralateral docking limb prior to deployment of the main body device can facilitate this step. It is imperative to confirm that the cannulating guidewire is actually within the body of the main endograft. There are a number of methods to confirm entry into the main aortic graft, but the surgeon should use that which he/she is most comfortable. The most definitive way to determine successful cannulation of the docking limb is to use IVUS, but this can be accomplished by a number of methods. A common method is to place a reverse curve catheter such as a SOS or a pigtail catheter into the main body at the level of the neck and spinning the catheter. If the catheter spins freely, this confirms that it is not outside of the endograft where it would be trapped between the aortic wall and endograft. Alternatively, an arteriogram can be performed using a catheter within the main body, confirming that dye fills the aortic graft, but not the aneurysm on initial injection. Once this is confirmed, the contralateral wire is advanced into the proximal descending thoracic aorta under fluoroscopic guidance and exchanged for a stiff wire using a catheter.

If IVUS is used, the hypogastric artery can be identified and marked during withdrawal of the catheter after confirmation of docking limb catheterization, and the length measured using the radiopaque marks on the IVUS catheter. Alternatively, placing the imaging equipment into the proper position for optimal visualization and a retrograde injection then performed through the sheath can mark the hypogastric. The optimal angle can be variable, and is best-determined using preoperative 3D imaging. If not available, the typical angle required to see the hypogastric is in the opposite obliquity about 300 from the side of the vessel (i.e., Right Anterior Oblique for the Left internal iliac artery). The location of the orifice is marked on the imaging screen and a marker catheter is used to measure the distance from the contralateral docking limb to confirm the preoperative measurements and device selection. The contralateral limb is then introduced over the stiff wire, appropriately positioned relative to the docking limb and the orifice of the internal iliac artery, and then deployed.

After deployment of all the devices, a compliant aortic occlusion balloon is advanced over the ipsilateral stiff wire and inflated in the region of the infrarenal neck to mold the proximal attachment sites. The aortic balloon is then withdrawn and gently expanded at the main body/iliac limb overlap zone and both distal iliac artery fixation sites. A completion arteriogram is then obtained using an angiographic catheter placed through one of the introducer sheaths ([Fig. 96-11](#)). The arteriogram should adequately evaluate the proximal/distal fixation sites, the graft/graft overlap zones and the orifices of the renal/internal iliac arteries. In addition, it should include delayed imaging to help identify any endoleaks. Problems identified on the completion study should be corrected, if possible. The potential remedial procedures include balloon dilation or aortic/iliac extension cuffs.

Figure 96-11. Completion arteriogram after an endovascular aneurysm repair is shown. The arrow marks the caudal extent of the stent graft. Note that the iliac limbs have been intentionally crossed to facilitate the cannulation of the contralateral gate.

With open femoral exposure, all sheaths, catheters, and wires are removed after the completion of the arteriogram and the femoral arteriotomy closed using the previously placed purse-string suture. When using percutaneous closure methods, the wire is typically left in during closure to allow placement of additional closure devices as necessary. Pedal Doppler signals should be confirmed prior to removal of the wire and completion of arterial closure. The heparin can then be reversed with protamine (1 mg protamine/100 units heparin) after adequate signals are detected in the feet. The groin wounds are closed in layers with absorbable suture and the final skin later is closed with a subcuticular technique.

The immediate postoperative course is typically fairly uneventful. Patients are transferred to the general care ward after recovery in the postanesthesia care unit. Patients are started on an appropriate diet the evening of the procedure and encouraged to get out of bed. Patients should be kept supine for 4 to 6 hours after the operation when a percutaneous technique is used to ensure successful hemostasis. Plain radiographs of the abdomen (4 views, optimized for metal) can be obtained on the first postoperative day for a baseline position of the grafts, but this is not routine in many centers. Most infrarenal EVAR patients are discharged home on postoperative day 1 or 2, and then seen in the outpatient clinic at 1 month with an abdominal/pelvic CT scan. It is important to note that mild fever and the finding of air around the graft on CT are common occurrences immediately after endograft repair and have not been associated with graft infection.²²⁷

9 It is imperative that patients are followed long-term given the uncertainty associated with the endovascular repair and the need for remedial procedures. As noted above, new endoleaks have been identified many years after repair.²²⁸ A variety of protocols and imaging techniques have been described although an abdominal/pelvic CT scan with contrast at 12 months and then yearly noncontrast studies seems reasonable in the absence of any identifiable problems and an aneurysm sac that is not increasing in size. Indeed, Sternbergh et al.²²⁹ reported from a multicenter trial that the absence of an endoleak at 1 and 12 months predicted favorable long-term outcome. More frequent imaging may be indicated if the aneurysm continues to grow or there is evidence of an endoleak. The surveillance CT scans should include noncontrast and biphasic contrast views with delayed images to help identify any late endoleaks.²³⁰ Calcified material will frequently be present in the aortic sac, and can masquerade as contrast. The noncontrasted portion of the CT will help determine the nature of this material and can be very helpful when combined with contrasted imaging. Although not part of all surveillance protocols, early plain radiographs are very helpful to identify structural changes/problems with the grafts, and are sometimes more useful than CT in identifying issues with the metal skeleton of the graft. Duplex ultrasound has been employed as a surveillance study, but its accuracy is dependent on the local expertise of the vascular laboratory.²³¹⁻²³³

Complications and Outcome

The mortality rates in the recent randomized trials and national series is less than 2%,^{69,70,74,111} the perioperative complication rate is <25%,^{73,136} the rupture risk is approximately 1%/yr,^{136,141} and the

incidence of remedial procedures approximately 10%/yr.^{145,234} Many of the same complications that can occur after open repair can occur after endovascular repair. However, the relative incidence of the various complications is significantly different, and several complications inherent to EVAR have been identified.

A variety of potential complications may arise during insertion of the delivery catheter or introducer sheath. Indeed, access problems secondary to iliac stenosis and/or tortuosity are the most common procedure-related complication. The outer diameters of the delivery sheaths are device-dependent, but can range up to 25 Fr. Device companies are diligently working to decrease the profile of their endografts, but the outer diameter of some endografts continues to be a limitation in some patients. The cross-sectional outer diameter of a sheath corresponds to a diameter of $1/\pi$ mm (e.g., 24 Fr = $24/3.14$ mm or 7.6 mm). A variety of techniques are available to correct or overcome small or diseased access vessels, and these should be factored into the preoperative plan. Excessive force during insertion of these large sheaths or delivery catheters can result in serious injury and perforation/disruption of the vessels. Predictably, this can lead to significant hemorrhage and hemodynamic changes. The diagnosis can be confirmed by arteriography and the bleeding controlled intraluminally using the device sheath or a balloon catheter. A variety of endovascular salvage techniques are possible in this setting including deployment of either the main device or a covered stent over the disrupted artery. Most major arterial disruptions can be managed with endovascular techniques, but in the event they are unsuccessful, a retroperitoneal incision with direct control of the iliac arteries can be performed expeditiously.

Safe conduct of an EVAR is predicated by sufficient knowledge of the various salvage techniques, the necessary catheter and guidewire skills to execute these techniques and a complement of ancillary equipment. However, the adage that “prevention is better than the cure” holds true and endovascular surgeons should maintain a low threshold for constructing a retroperitoneal iliac conduit prophylactically. Further, dissection within the arterial wall of the iliac vessels or aorta may also result from misdirection or excessive force during cannulation of the vessels. When nonflow limiting, no intervention may be necessary, but if flow limitation is noted, the dissection can usually be corrected by cannulating the “true” lumen and reestablishing its integrity by deploying a peripheral (uncovered) stent. If the wire is left in place until Doppler signal is confirmed in the feet, true lumen access is maintained, making this much easier.

Graft deployment can be associated with mechanical problems related to the delivery system or inappropriate positioning. A host of mechanical problems have been described, and the list will likely expand with widespread application of the devices and the introduction of updated systems. Many of the mechanical problems are device-specific and related to the actual sequence of events and manipulations required. Troubleshooting guidelines and specific recommendations are available from the manufacturers. Deployment of the endovascular graft below the proximal target site on the infrarenal aorta may be corrected using an aortic extension cuff. Attempting to reposition the graft further proximally after deployment has not been successful and is not recommended. Deployment of the endovascular graft across the orifices of the renal arteries can potentially be corrected by displacing the graft caudally. A guidewire can be passed over the flow divider and out the contralateral groin. The entire graft can then be retracted caudally by pulling on the wires. Alternatively, a large balloon can be inflated above the flow divider and retracted. Extreme care must be exercised during these maneuvers to prevent complete dislodgement of the proximal main body from the neck. Deployment of the graft across part of the renal orifice can be corrected by placing a stent within the lumen of the renal artery and, thereby, displacing part of the main body caudally. This may be done from the femoral access or may require arm access if more extensive unintentional coverage of the branch vessel has occurred. Deployment of the endograft across the lumen of one internal iliac artery is usually tolerated provided the contralateral vessel is patent and relatively free of occlusive disease. Indeed, it is relatively common to embolize a single internal iliac artery in patients with common iliac artery aneurysms to facilitate fixation of the graft limb in the external iliac artery. With coverage of a single hypogastric artery, severe complications are rare, but buttock claudication and impotence are not.¹²⁹ Occlusion of both internal iliac arteries or occlusion of one vessel in the presence of contralateral disease may render the pelvis ischemic. In the event of unintentional hypogastric artery coverage, the iliac limb can be pushed cephalad using a sheath and its dilator. It should be emphasized that many of these remedial procedures are not manufacturer approved and should only be attempted by experienced endovascular surgeons. Due to the advanced age of many of these patients and their attendant comorbidities, open surgical conversion should be contemplated only as a last resort after the endovascular options have been exhausted, again emphasizing the need for advanced endovascular skills.

It is relatively common to see an endoleak on the completion arteriogram. Treatment is contingent upon the specific type of leak and their associated natural history although the majority of these early endoleaks ultimately resolve.²³⁵ Type 1a/b (a-proximal, b-distal attachment site) and type 3 (fabric tear or modular component separation/leak) endoleaks are particularly concerning and every reasonable attempt to correct these defects should be made. The aneurysm sac is often exposed to systemic pressure in the presence of a type 1 or type 3 endoleak, and, therefore, the rupture risk likely approaches that associated with the untreated aneurysm. Both the type 1 and 3 endoleaks can potentially be corrected by repeat balloon angioplasty at the proximal/distal attachment sites or at the modular interface. If these measures are not successful, additional extension devices can be deployed. With the exception of large proximal type 1 endoleaks, it is reasonable to manage most perioperative endoleaks expectantly since many seal spontaneously after reversal of the anticoagulation or within the first 6 months. Indeed, even type 1a endoleaks often thrombose before the first postoperative imaging study, although patient selection, aneurysm diameter, and risk of rupture should be carefully considered before leaving an endoleak of this nature. Thus, the surgeon should be mindful that the inability to obtain a satisfactory exclusion of the aneurysm at the time of endograft implantation does not mandate a surgical conversion at the same setting. In situations where there is concern for a persistent endoleak, an earlier postoperative CT than the usual 1-month study may be advisable.

In the event that a significant endoleak persists on postoperative imaging, the potential options include referral to another center with more expertise and branched/fenestrated capabilities, open surgical repair with removal of any or all implanted devices, or no further treatment if the patient is a poor surgical risk. Type 2 endoleaks (retrograde branch vessel related) have a relatively benign natural history and do not merit aggressive intervention unless the aneurysm continues to increase in size over time. Type 4 (trans-graft) endoleaks are self-limiting, and do not merit treatment at all. They are identified as a diffuse contrast “blush” at the time of the completion arteriography. They represent a diagnosis of exclusion and mandate that the more worrisome type 1 endoleak be excluded.

The spectrum of immediate postoperative complications after EVAR is comparable to that outlined for after open repair and will not be repeated. However, the incidence of major, systemic complications after EVAR is quite small. It is noteworthy that the incidence of both paraplegia and bowel ischemia are comparable after endovascular and open repair although the mechanisms are different and likely due to atheroembolism.^{210,236,237} Indeed, diffuse embolization to the small bowel has been reported after endovascular repair and is almost uniformly fatal.²³⁶

The long-term complications after EVAR include endoleak, structural failure, need for remedial procedures, need for open conversion, and rupture. These ongoing risks further emphasize the importance of conscientious lifelong surveillance. All type 1 and 3 endoleaks identified during surveillance merit further evaluation and correction given their ongoing rupture risk. Device migration has been reported to cause type 1 endoleaks and has been associated with neck length, site of deployment below the renal arteries, and surgeon/center experience.²²² The treatment of these late occurring type 1 and 3 leaks is identical to that for those occurring earlier and includes identification of the specific site and remediation with either balloon angioplasty or an additional endovascular device, although the latter is most common. Type 2 endoleaks merit intervention and treatment if the aneurysm continues to increase in diameter, although the clinical scenario is an important deciding factor in these cases. Identification of the type 2 endoleak can be challenging and may require selective catheterization of the superior mesenteric or internal iliac arteries.²³⁸ A variety of approaches have been described to treat the type 2 endoleaks including coil embolization, laparoscopic ligation of the feeder vessels, and direct translumbar or transcaval injection of the aneurysm sac with glue or other thrombotic agents.^{239,240}

Aneurysms that continue to increase in size after EVAR merit further intervention and may require open conversion due to their ongoing rupture risk. Continued aneurysm growth has been associated with the type of prosthesis and baseline size in addition to the presence of endoleak.¹⁴⁷ It should be emphasized that the goal of aneurysm repair is to prevent rupture/death from rupture and that endoleak and even sac enlargement are surrogate markers of potential late failure of the therapy. Indeed, even the clinical significance of an enlarging sac in the absence of a visible endoleak is controversial as long as a secure proximal and distal fixation of the endograft has been demonstrated. To confound the issue further, rupture of aneurysms without an endoleak or a change in sac diameter has also been reported, leading some to describe the phenomenon teleologically as endotension. A presumed endoleak that is not detected on a properly performed contrast CT scan is typically not identified on a catheter-based arteriogram. The proper diagnostic investigation of an endoleak should

include interrogation of all the fixation sites and modular interfaces and selective injections of mesenteric and hypogastric arteries with sufficient contrast dose and proper acquisition techniques. It should be emphasized that open conversion and explant of the endovascular graft can be technically more challenging than a de novo open repair and usually requires suprarenal or supraceliac aortic control. In the absence of infection, it is not always possible (or necessary) to remove the entire device, particularly when the device has suprarenal fixation. It is possible to transect the endovascular graft near the usual site of the infrarenal aortic anastomosis and incorporate the fabric/stents of the graft into the anastomosis. Temporary distal vascular control can be achieved by clamping the limbs of the endovascular graft. The limbs of a bifurcated surgical graft may be anastomosed directly to the endograft limbs if they are securely attached to the iliac artery. In properly chosen elective patients, open conversion can be performed with similar outcomes to primary open juxtarenal AAA repair.²⁴¹

A variety of device-specific complications, including strut fracture, fabric tears, and buckling of the graft, have been identified, and the list will likely increase with the introduction of newer technologies. Importantly, these may present at any time throughout the postoperative period. An extensive discussion of all the potential device-related complications and their treatment is beyond the scope of this chapter. Importantly, regression of the aneurysm, although typically desirable, has been associated with significant conformational changes in the endografts and has resulted in limb thrombosis and disruption of the distal attachment sites.²⁴² These adverse outcomes in the presence of decrease in the aneurysm size have been termed the “paradox of success.”

REPAIR OF RUPTURED ABDOMINAL AORTIC ANEURYSMS

Open Repair

The approach to the patient with a ruptured AAA is similar to the elective scenario with the exception of several points that merit further comment. In order to achieve a reasonable result, the diagnosis should be made in an expeditious fashion and the appropriate treatment initiated quickly. The endovascular approach appears to be associated with a lower mortality rate, but this remains to be further documented given the inherent bias in terms of patient selection and publication.^{85,86,88-90}

The patient should be taken emergently to the operating room once the diagnosis of a ruptured aneurysm has been made. Unnecessary delays to complete the preoperative evaluation should be avoided. Unfortunately, the diagnosis is not always made in a setting where an operating room and the appropriate resources are immediately available. In this scenario, the patient should be transferred to the appropriate setting as quickly as possible, which may require transfer to a facility able to provide a higher level of care. When the decision is made to transfer a patient with a ruptured aneurysm, the transferring physician should keep several principles in mind, with the most important being avoidance of hypertension and the concept of permissive hypotension.²⁴³

When bringing the patient to the operating room, the OR team and anesthesia personnel should be notified immediately upon diagnosis and instructed that the patient is en route. The necessary instrument trays should be opened, the room temperature in the operating room increased, adjunctive measures to maintain body temperature obtained, and the intraoperative autologous salvage device prepared. Notably, hypothermia has been shown to be a strong, independent predictor of mortality after ruptured aneurysm repair.²⁴⁴ The blood bank should be notified and instructed to send 6 units of blood to the operating room. This should be type O negative or type-specific if cross-matched units are not available. Furthermore, the blood bank should be instructed to expedite the cross-match of additional red blood cells, fresh frozen plasma, and platelets.

On arrival at the operating room, the patient should be prepared and draped before intubation and the induction of anesthesia, which includes draping from chin to knees or toes, depending on the surgeon's preference. This allows access to both groins for endovascular proximal control, and the chest in the event that resuscitative thoracotomy is required. During the patient preop, the surgeon and assistants should gown/glove and be prepared to make the incision at the time of induction, because patients with ruptured aneurysms frequently become hypotensive after the induction of anesthesia.

A midline incision should be made and supraceliac aortic control obtained. The aorta/esophagus can be difficult to identify, especially in a hypotensive patient during a deluge of blood from the abdomen. A nasogastric tube placement quickly after induction makes identifying the gastroesophageal junction much easier, and thus the proper location of the supraceliac clamp. The esophagus should be manually moved to the patient's left and the gastrohepatic ligament, the crus of the diaphragm, and the

connective tissue enveloping the aorta can be divided using blunt finger dissection. If necessary, control of the aorta can be achieved manually by either occluding the aorta between the fingers and thumb or compressing it against the vertebral bodies. Definitive control should be obtained with an aortic clamp. Of course, care should be utilized during these maneuvers to prevent injury to the esophagus or the aorta itself.

Aortic control can also be achieved through a variety of other means: thoracotomy with occlusion of the descending thoracic aorta, intraluminal control of the infrarenal aorta with a compliant balloon placed through a femoral artery, or supraceliac control via a retroperitoneal incision, if that approach was chosen. The aortic surgeon should be familiar with these various techniques because they can be helpful in certain clinical settings, but the midline approach with supraceliac control is recommended for most ruptured *infrarenal* aneurysms. After supraceliac aortic control has been obtained, the infrarenal aorta is dissected and vascular control is achieved below the level of the renal arteries. The hematoma from the ruptured aneurysm often facilitates the dissection by displacing the normal tissue planes. However, the normal tissues may be obscured, and care should be taken not to injure the venous structures, particularly the left renal vein, which can lead to much more blood loss. The supraceliac aortic clamp can be released after infrarenal control has been obtained, and flow can be restored to the visceral vessels. It is imperative that these various steps are coordinated with the anesthesia team, and it is recommended that the supraceliac clamp be left in position to facilitate reapplication if necessary. Distal vascular control can be achieved with either vascular clamps or intraluminal balloons, depending on the character of the iliac vessels.

Patients can be heparinized after proximal and distal vascular control has been obtained, provided that the patient is doing well and the case is proceeding expeditiously.²⁴⁵ However, the decision to anticoagulate the patient is contingent on a variety of factors, including the quantity of blood lost, presence of coagulopathic bleeding, body temperature, and hemodynamic status. Anticoagulation potentially reduces thrombotic complications, but it exacerbates coagulopathic bleeding. Before completion of the distal anastomoses, thromboembolism catheters should be passed distally through the iliac vessels to remove any thrombus or debris. It is recommended that the inferior mesenteric artery be implanted (if patent) to reduce the risk of postoperative colonic ischemia. The heparin effect can be reversed with protamine after confirmation of distal lower-extremity arterial signals. The administration of plasma, platelets, or both should be considered at this point if any evidence of coagulopathic bleeding is noted. A thromboelastogram (TEG) can be very helpful in determining the need for supplemental blood products.²⁴⁶

The postoperative course after repair of a ruptured aneurysm is predictably more complicated and protracted than after elective repair.^{247–251} Both the intensive care unit and total hospital length of stay are significantly increased. The mortality and complication rates are likewise significantly increased. As noted above, the mortality rate for patients with ruptured AAAs who make it to the operating room is approximately 50%.¹³ The spectrum of postoperative complications after repair of a ruptured aneurysm is essentially the same as after elective repair although the incidences are increased. The incidence of bowel ischemia may be as high as 40% and routine colonoscopy may be indicated.²¹¹ Abdominal compartment syndrome^{252,253} and adrenal insufficiency²⁵⁴ have been reported after ruptured aneurysm repair and merit consideration in patients that are not doing well. Notably, adrenal insufficiency was identified in almost 70% of patients with unexplained postoperative hypotension after ruptured aneurysm repair.²⁵⁴ Predictably, long-term survival is decreased relative to patients undergoing elective repair²²⁵ although the overall quality of life is comparable.²⁵⁵

ENDOVASCULAR REPAIR FOR RUPTURE

EVAR has the potential to greatly impact the operative mortality rate for ruptured AAAs, but depends heavily on aortic anatomy, more so than for open repair. Although the worldwide experience is relatively small, early outcomes are impressive, particularly given the significant mortality/morbidity associated with the open repair which has remained relatively constant over the past few decades.⁸³ Despite the appeal of the endovascular approach, its application requires a defined protocol/approach consisting of an experienced endovascular surgeon, a committed team, an available operating room with the necessary imaging equipment, and an inventory of suitable devices. Several recent studies have estimated that approximately 20% to 50% of patients with ruptured aneurysms are anatomically suitable for endovascular repair using conventional devices although this number may increase with the introduction of newer devices and/or the extension beyond the manufacturers' IFU.^{256–258}

The endovascular approach for the treatment of ruptured AAAs can be briefly summarized and has been described by multiple authors.^{259,260} Patients with a presumed diagnosis of a ruptured AAA that are hemodynamically stable, as defined by a systolic blood pressure >80 mm Hg and normal mentation, should undergo a rapid CT arteriogram to determine their anatomic suitability. Notably, aggressive fluid resuscitation should be avoided during this period to avoid the risk of releasing the retroperitoneal tamponade. The anatomic criteria for EVAR include an acceptable neck anatomy (length ≥ 10 mm, diameter ≤ 32 mm, freedom from prohibitive angulation [device specific]) and adequate access vessels (≥ 7 mm diameter). The operative plan is generated and the appropriate devices selected based upon the CT findings and patients are taken directly to the operating room from the scanner. Oversizing of the aortic neck $\geq 20\%$ and encroachment on the orifices of the renal arteries with adjunctive stenting are both tolerated in an attempt to limit the necessary inventory and increase the proximal fixation zone, respectively. Access to the common femoral arteries is obtained using a percutaneous approach with direct exposure and repair delayed until the completion of the procedure. In the absence of severe hypotension, the remaining conduct of the procedure is essentially the same as described in the elective setting. It is not usually necessary to occlude the aorta with an intraluminal balloon although one should be readily available in the event that the patients become hemodynamically unstable.^{261,262} The criteria for an acceptable result are somewhat less in the emergent setting and persistent attempts to achieve a perfect radiographic result should be avoided. The ultimate goal is to prevent further hemorrhage and to allow the patient to be resuscitated, which does require the absence of a type I or III endoleak, but otherwise does not require an absolutely perfect radiographic result. Further interventions including conversion to open repair may be necessary at a later date, but these can usually be performed in an elective fashion.

Notably, patients treated with EVAR are at risk of developing abdominal compartment syndrome, which can be related to intra/retroperitoneal hemorrhage and/or aggressive volume resuscitation. The surgeon should consider prophylactic celiotomy or retroperitoneal evacuation with placement of an open abdominal dressing at the conclusion of the procedure, which may be required in up to 20% of patients.^{263,264}

ADDITIONAL CONSIDERATIONS

Isolated Iliac Artery Aneurysms

Isolated iliac artery aneurysms are rare and have been reported to occur with an incidence ranging from 0.03% in autopsy series¹¹ to 2.2% in single-institution series.²⁶⁵ The common iliac artery is involved in approximately 70% of the cases, and the internal iliac artery in the remainder.²⁶⁶ Aneurysmal involvement of the external iliac artery, either in combination with the common iliac artery or alone, is distinctly rare. These isolated iliac artery aneurysms should be differentiated from the common iliac artery aneurysms that occur concomitantly with AAAs. Simultaneous aneurysmal involvement of the aorta and common iliac arteries occurs in about 10% to 20% of all AAAs^{11,12}; this pattern should be considered as one disease process and treated accordingly.

The natural history of isolated iliac artery aneurysms is poorly defined because of their low incidence. The clinical risk factors appear to be similar to those for AAAs with the highest incidence seen among elderly men. Unlike patients with AAAs, a significant proportion of patients with isolated iliac artery aneurysms present with symptoms.²⁶⁶ These symptoms may result from either rupture or compression of adjacent structures including the bowel, ureters, iliac veins, and nerves. The clinical presentation of patients with a ruptured iliac artery aneurysm is similar to that of ruptured AAAs, and the diagnosis should be included in the differential for patients with genitourinary symptoms and normal findings on urinalysis and testicular examination. CT arteriography is optimal for confirming the diagnosis of an isolated iliac artery aneurysm. The utility of ultrasonography is limited by the posterior course of the iliac vessels and the overlying bowel. Large iliac artery aneurysms may occasionally be palpated during rectal or gynecologic examination, and ruptured iliac artery aneurysms may present with ecchymosis of the perineum.

The principles of treatment for asymptomatic, isolated iliac artery aneurysms are similar to those for AAAs, and operative repair is justified when the risk for rupture offsets the risk of repair. Unfortunately, the natural history of isolated iliac artery aneurysms and the appropriate threshold for repair remain unresolved. The reported growth rate for iliac artery aneurysms <3 cm is 0.11 cm/yr while that for aneurysms 3 to 5 cm is 0.26 cm/yr.²⁶⁷ Although rupture has been reported for aneurysms smaller than 2

cm, it is rare for aneurysms smaller than 3 cm to rupture.^{265,268} Operative repair is generally recommended for good-risk patients with isolated iliac artery aneurysms ≥ 3.5 cm. The frequency of surveillance imaging studies should be dictated by the size of the aneurysm with yearly studies appropriate for aneurysms < 3 cm with 6 month intervals appropriate for aneurysms between 3 and 3.5 cm.²⁶⁵

The treatment or repair of isolated iliac artery aneurysms depends on the specific vessel involved and the extent of the aneurysm. Theoretically, common iliac artery aneurysms can be repaired with an interposition graft or a covered stent provided that there is a sufficient proximal and/or distal neck to sew the anastomosis or seat the graft. However, this is rarely an option because the aneurysm involvement of the vessel usually extends over its whole length. Therefore, repair necessitates replacing the whole common iliac artery with a bifurcated graft similar to the approach for patients with combined aortic and iliac artery aneurysms. Both open and endovascular approaches are available and the concerns about the individual choice (i.e., open vs. endovascular) are likely similar to that outlined for AAAs. In addition, the principles of treatment for both the open and endovascular approach of isolated iliac artery aneurysms are similar to AAAs. In the case of open repair, the proximal anastomosis should be performed immediately below the renal arteries to prevent subsequent aneurysm degeneration of the infrarenal cuff while the distal anastomosis should be performed at the common iliac bifurcation on the involved side. The distal anastomosis on the uninvolved common iliac artery can be performed to a nonaneurysmal segment. For the endovascular repair, the graft should be seated immediately below the renal arteries and at the takeoff of the internal iliac artery on the side opposite the aneurysm. The iliac limb on the side of the aneurysm is seated in the external iliac artery and necessitates embolization, branched stent graft, or open surgical bypass of the ipsilateral internal iliac artery.

The treatment of internal iliac artery aneurysms is typically exclusion. This can be performed using either an endovascular or open approach although the former is likely preferred due to its simplicity. Bypass of an internal iliac artery aneurysm is often not possible because there is rarely a proximal or distal neck. Indeed, the aneurysmal involvement usually extends to the common iliac bifurcation and the distal aspect usually arborizes into multiple smaller vessels. The principles of the endovascular treatment include obliterating both the arterial inflow and the outflow of the aneurysm. The outflow is usually occluded using selective coil embolization, although a variety of other agents, such as glues and gelfoam, have been described. Placing a covered stent across the orifice of the internal iliac extending from the common to the external iliac vessels eliminates the inflow. The open approach requires vascular control of the distal common iliac and proximal external iliac arteries. The internal iliac artery is then opened by incising the aneurysm, and the branches are oversewn from within. The proximal internal iliac artery can be either oversewn at its takeoff, or the resultant defect at the common iliac bifurcation can be repaired with patch angioplasty. The appropriate treatment for patients with bilateral internal iliac artery aneurysms remains unclear. Exclusion of both vessels has the potential to cause severe pelvic ischemia that may not be remediable. A conservative approach is likely justified in this setting with a higher threshold for intervention appropriate for the second vessel. Treatment options include excluding only the larger vessel, attempted revascularization, and staged exclusion after sufficient time has elapsed to facilitate potential collateral development. Regardless of the treatment option, it is important to assess the status of the pelvic circulation including the profunda femoral artery and the inferior mesenteric artery, which are important collaterals to the pelvis.

INFLAMMATORY ABDOMINAL AORTIC ANEURYSMS

Approximately 5% of all AAAs are described or considered inflammatory.²⁶⁹ These are characterized by a dense inflammatory response encasing the anterior and lateral walls of the infrarenal aorta with sparing of the posterior aspect. The inflammatory response consists of a dense cellular infiltrate that has a white, glistening appearance on inspection. The inflammation results in an increase in wall thickness with the difference between the inner and outer diameters of the aorta ranging from 1 to 5 cm. The cause of this inflammatory process remains unresolved, but it is likely an autoimmune phenomenon. Indeed, some type of autoimmune disorder has been identified in up to 20% of patients with inflammatory aneurysms.²⁷⁰

Patients with an inflammatory abdominal aneurysm are predominantly male and frequently present with symptoms of back or abdominal pain. The triad of a pulsatile abdominal aortic mass, abdominal pain, and an elevated erythrocyte sedimentation rate (ESR) has been described. Abdominal

ultrasonography or CT may confirm the diagnosis. The anterior and lateral aspects of the aortic wall are thickened and hypoechoic on the sonogram. The CT findings are characteristic and include a thick, contrast-enhancing wall in the distribution described. An inexperienced observer may confuse the CT findings with those of a ruptured AAA. Hydronephrosis with *medial* displacement of the ureters is frequently seen in contradistinction to the lateral displacement seen with noninflammatory aneurysms. Indeed, this entity may share some pathophysiologic pathways with retroperitoneal fibrosis.

The treatment of inflammatory AAAs is essentially the same as that for the more common, noninflammatory variety. Nonoperative treatment with corticosteroids has been advocated in the past, although this approach is likely ineffective and has largely been abandoned.²⁷¹ It has been suggested that the rupture risk of inflammatory aneurysms is less than that for noninflammatory variety because the wall thickness is increased. However, this is not true, and patients should not be lulled into a false sense of security. It should be emphasized that most aneurysms rupture through their posterior or posterolateral aspect, which is not involved in the inflammatory process. The open repair of an inflammatory AAA is complicated by the fact that the adjacent structures, including the duodenum, colon, and ureters, may be involved in the process and densely adherent to the aortic wall. Using the retroperitoneal approach can reduce the technical difficulties associated with the open repair. The operative blood loss and procedure time associated with the open repair of inflammatory AAAs may be greater than the more common, uninvolved type. These potential technical difficulties should be factored into the operative indications and size-related threshold for the open approach.

EVAR may be the optimal treatment for patients with inflammatory AAAs due to the concerns about the inflammatory process and adherent structures outlined above.^{272–275} Notably, Puchner et al.²⁷⁵ performed a meta-analysis of patients undergoing endovascular repair for inflammatory aneurysms and reported that the inflammatory process resolved in approximately 50% of the cases. Inflammatory aneurysms can be repaired through a transperitoneal approach, and this scenario occasionally arises when the diagnosis is not suspected preoperatively. Regardless of the open approach, no attempt should be made to mobilize the adherent structures, specifically the duodenum, because of the potential for accidental injury. Proximal aortic control can be achieved either immediately above the renal arteries or above the visceral vessels. Alternatively, intraluminal aortic control can be achieved with a balloon catheter, although this approach is less appealing. Distal control can usually be achieved at the common iliac arteries or at the level of their bifurcation. The duodenum and other adherent structures should be mobilized by incising the wall of the aneurysm and then reflecting them laterally. The proximal anastomosis can usually be performed to the infrarenal aorta from the inside of the aneurysm after opening the wall. The preoperative placement of ureteral catheters, particularly lighted catheters if available, may facilitate their identification intraoperatively and can be helpful in patients with hydronephrosis. An increased incidence of anastomotic pseudoaneurysms has been demonstrated in patients with inflammatory aneurysms after open repair and justifies long-term surveillance.^{276,277}

Juxtarenal and Suprarenal Abdominal Aortic Aneurysms

The management of aneurysms extending to the level of the renal arteries or more cephalad is more complicated, and, predictably, the morbidity and mortality rates associated with open repair are increased.^{278–280} Interestingly, several recent reports from centers of excellence have documented mortality rates comparable to those reported for infrarenal repairs although it is unlikely that these findings are applicable nationwide.^{281–283} Repair of these complex aneurysms is complicated by the obligatory period of renal and visceral ischemia associated with aortic occlusion during the proximal anastomosis. Indeed, the renal complication rates range from 15% to 20% even from these select centers of excellence.^{281–283} These increased morbidity and mortality rates should be factored into the decision algorithm and threshold for operative repair. Elective operative repair is usually recommended for patients with aneurysms 6 cm or larger in diameter in this setting although the 5.5-cm criterion may be appropriate for very good-risk patients and those with juxtarenal aneurysms who will require only a short period of suprarenal aortic occlusion.

AAAs extending to the renal arteries or more cephalad may be repaired via either a retroperitoneal or a transperitoneal approach although the former is optimal, especially with more cephalad disease. The *retroperitoneal* approach, with anterior reflection of the left kidney, obviates the concerns about the left renal vein (except when a retroaortic renal vein is present) and simplifies exposure of the abdominal aorta. The distal descending thoracic aorta is easily exposed by incising the diaphragm and its crus. Of note, the right renal artery and right common iliac artery are more difficult to expose via the retroperitoneal approach because of their trajectory of those vessels, but this is not prohibitive in most

cases. The proximal anastomosis may be fashioned as a long beveled anastomosis incorporating the orifices of the renal and visceral arteries, or a Carrel patch can be fashioned from the aortic segment with reimplantation or bypass of the left renal artery in situations where the aneurysm involves the entire visceral segment.

For juxtarenal aneurysms repaired through the *transperitoneal* approach, the aorta can be clamped in the supraceliac or suprarenal position, depending on the extent of the disease and the patient's body habitus. Suprarenal clamp is preferred to avoid unnecessary visceral ischemia. Of course, if the aneurysmal tissue extends above the renal arteries, a supraceliac clamp may be required. The supraceliac exposure is similar to that described above for a ruptured infrarenal AAA, but performed in a more controlled fashion. After mobilization of the left lobe of the liver, the esophagus should be reflected left laterally. Placement of a nasogastric tube facilitates identification of the esophagus/gastroesophageal junction. The gastrohepatic ligament should be divided making note of aberrant hepatic arterial anatomy to avoid dividing a replaced hepatic vessel during this portion of the dissection. The crus of the diaphragm can be divided bluntly or sharply followed by division of the dense connective tissue surrounding the aorta for placement of the clamp. If a clamp is to be placed in the suprarenal position, this is facilitated by retracting the left renal vein superiorly or inferiorly after ligating its adrenal, gonadal, and lumbar branches. As noted previously, the left renal vein may be ligated near its confluence with the vena cava without adverse sequelae.²⁰⁶ The collaterals of the left renal vein (e.g., adrenal) should be preserved when using this approach; thus, the decision to divide this vessel should be made early. The anterior surface of the aorta at the level of the visceral vessels is encased by dense neural tissue, which can be incised. Incising the crus of the diaphragm that envelops the lateral aspect of the aorta further facilitates clamp application. The configuration of the proximal anastomosis in the setting of the transperitoneal approach depends on the extent of the aneurysm and the vessels involved.

EVAR for juxtarenal AAAs has become widely available with the FDA approval of fenestrated aortic grafts.^{8,284–287} The approach is based upon constructing a suitable landing zone for the more traditional endograft in patients with an inadequate or short infrarenal neck. This is accomplished using an individually designed fenestrated endograft that contains orifices that correspond to the renal and visceral vessels. These fenestrations permit the introduction of individual covered stents. The worldwide experience with fenestrated EVAR is vast, and the technique has been shown to be feasible, safe, and to prevent aneurysm rupture in the short term.^{8,284–287}

Further progression of repair into the visceral segment with branched/fenestrated repairs using custom aortic grafts, surgeon-modified devices, and parallel stent techniques such as “chimney” EVAR are an ongoing revolution in aortic repair, and have demonstrated acceptable results in both elective and urgent/emergent clinical scenarios. The profound complexity in the device-to-device and device-to-aorta/branch vessel interactions with these types of repair certainly make their durability questionable, and close follow-up of these patients is warranted.^{288,289}

Combined endovascular and open (i.e., “hybrid”) approaches have also been used to treat the juxtarenal and more complex proximal aneurysms. These techniques are based upon constructing a suitable aortic neck to land a traditional endograft by “debranching” the renal or visceral vessels. For example, a suitable landing zone below the superior mesenteric artery (SMA) could be created for a juxtarenal aneurysm by performing bilateral iliorenal bypasses. Although theoretically appealing, a number of reports have demonstrated that mortality rates for the hybrid approach for complex aneurysms have been comparable to open repair, and these repairs have largely fallen out of favor in many centers.^{290–292} Indeed, the magnitude of the revascularization procedure appears to be comparable to that of the more traditional open repair and, accordingly, the approach does not appear to extend the indications for aneurysm repair to older, sicker patients. Thus, branched/fenestrated repairs may be more suitable in these patients, if a repair is warranted at all.

Infected Abdominal Aortic Aneurysms

Infected AAAs comprise a small subset of all AAAs, accounting for less than 1% of all repairs.²⁹³ The term *mycotic aneurysm* coined by William Osler to describe aneurysms that developed after septic cardiac emboli caused an arterial infection, has often been used to refer to all infectious etiologies for aneurysms. Unfortunately, “mycotic” is a misnomer that has led to a significant amount of confusion. A more specific classification system consists of four groups based on the underlying mechanism: (a) classic “mycotic aneurysm” caused by embolus from the heart infecting an artery; (b) microbial arteritis, in which bacteria infects an atherosclerotic but nonaneurysmal artery and leads to aneurysmal

degeneration; (c) an existing aneurysm that becomes infected; (d) traumatic pseudoaneurysm with concomitant bacterial inoculation.²⁹⁴ Microbial arteritis resulting from hematogenous bacterial spread currently accounts for approximately 80% of all cases of infected aortic aneurysms.^{295,296} *Salmonella* causes approximately 40% of all aneurysmal infections in contemporary series with the remainder caused by *Staphylococcus*, *Streptococcus*, *Bacteroides*, *Arizona hinshawii*, *Escherichia coli*, and *Pseudomonas aeruginosa*.²⁹⁴

The diagnosis of infected aortic aneurysm is often difficult and the clinical presentation insidious. Patients may present with fever, back/abdominal pain, or both. The physical examination is often remarkable for a palpable abdominal mass and the presence of peripheral emboli. Laboratory studies are notable for an elevated leukocyte count and positive blood cultures although the latter are present only 50% of the time^{296,297} and negative blood cultures do not exclude the diagnosis. CT is the most useful diagnostic study, and the features suggestive of an infected aneurysm include a periaortic mass, an aneurysm in an atypical location, periaortic fluid or gas, retroperitoneal inflammation, and frank rupture. The angiographic finding of a saccular or eccentric/irregularly shaped aneurysm in an atypical location is also suggestive of an infected aneurysm.

The treatment of an infected aneurysm requires control of hemorrhage in the presence of rupture, aggressive debridement of all infected tissues, and restoration of perfusion to the viscera and lower torso. Indeed, these treatment concerns and the management options are identical to those for patients with infected aortic grafts, which is a more common problem. Patients should be started on broad-spectrum antibiotics when the diagnosis is suspected although antibiotic therapy alone is not sufficient and the operative intervention should not be delayed in an attempt to sterilize the retroperitoneum. Patients with suspected rupture should undergo emergent exploration through either a transperitoneal or retroperitoneal approach. After vascular control has been obtained, the retroperitoneum should be explored, and intraoperative cultures along with stat Gram stain should be obtained. Several options for arterial reconstruction are available, depending on the clinical scenario and the individual patient's anatomy. These options include in situ replacement with a prosthetic or cadaveric graft, ligation of the infrarenal aorta with extra-anatomic bypass (axillo-femoral, femoral-femoral configuration), or in situ replacement with staged extra-anatomic bypass and subsequent removal of the in situ graft. The choice is contingent on the character of the aorta, degree of inflammation in the retroperitoneum, suspected organism, and hemodynamic status. In situ replacement of the infected aneurysm with a prosthetic or cadaveric graft is a reasonable option if retroperitoneal inflammation is minimal and the Gram stain is negative. The integrity of the aortic stump at the time of ligation and the potential for dehiscence or breakdown of the suture line are major concerns. The aorta should be debrided back to grossly uninvolved tissue and sutured in two layers with a running horizontal mattress and a simple continuous technique using nonabsorbable monofilament suture. A pedicle of omentum can be mobilized and approximated next to the aortic stump to help control the retroperitoneal inflammation and minimize the risk for stump dehiscence. When the diagnosis is suspected preoperatively and no evidence of rupture is found, a staged approach with extra-anatomic bypass followed by graft removal may decrease the physiologic impact of any one procedure. The procedures are usually performed 2 to 3 days apart to allow the patients a period of recovery. Patients should be anticoagulated between procedures to prevent thrombosis of the extra-anatomic bypass resulting from competitive flow. Fortunately, the risk of graft thrombosis and graft infection during the intervening period is small.

Endovascular repair of infected aortic aneurysm has been reported and can be considered an additional alternative.²⁹⁸ Although the long-term safety of EVAR in this clinical scenario remains unclear, it may serve as a temporizing approach that converts an urgent problem to an elective one. A recent meta-analysis by Kan et al.²⁹⁹ reported that the endovascular approach was reasonable, but the incidence of subsequent endograft infection was significant in patients with ruptured aneurysms and those with fevers. They concluded that endovascular repair could be used as a bridge in this setting (i.e., ruptured aneurysm, febrile) prior to definitive open repair.

Infected aneurysms involving the suprarenal aorta pose a particularly challenging problem, but fortunately are uncommon. In situ replacement with a prosthetic or cadaveric graft is frequently the only available option, which can be accomplished in a number of ways, but the principle of aggressive removal of all infected tissue should be adhered to in order to avoid recurrent infection, which is typically a fatal event. If the thoracic aorta is of good quality, an antegrade debranching of the visceral segment can often be accomplished, and limits the ischemia time to the visceral/renal vessels. If there is a contained rupture of the aorta, or the tissues are particularly inflamed, it may be best to obtain proximal and distal control above and below the disrupted/infected segment before attempting to

dissect the visceral/renal vessels from the inflammatory mass, which may rupture during dissection. After obtaining sites for proximal and distal aortic control, a branched prosthetic graft soaked in Rifampin is sewn to the aorta in an end-to-side manner using a side-biting clamp on the thoracic aorta, allowing antegrade perfusion during the anastomosis. It is important to leave enough good aorta below this bypass to allow a cross-clamp and separate end-to-end anastomosis. The left renal, SMA and celiac artery can be bypassed individually in some cases and then a cross-clamp placed on the aorta distal to the end-to-side graft. The aorta is then transected and aggressively debrided leaving just the right renal origin, when possible. A separate tube or bifurcated graft can then be sewn from the distal thoracic aorta to the bifurcation of the abdominal aorta, or to the iliac/femoral arteries, as indicated. This technique limits the ischemia time on the individual viscera/renal arteries, and allows full removal of all atherosclerotic material and infected aorta along with the infected periaortic tissues after complete revascularization of the visceral segment.

Patients with infected aneurysms, regardless of the arterial reconstruction, require long-term antibiotics and follow-up. Patients should receive intravenous broad-spectrum antibiotics until cultures are available, with the total of 6 weeks of intravenous antibiotics. If culture-directed therapy is not possible, broad-spectrum antibiotics for 6 weeks is indicated. The patient should then be placed on oral antibiotics although the duration of treatment remains unresolved and many surgeons will treat the patient with lifelong suppressive antibiotics. In addition, patients should undergo serial CT scans to assess the retroperitoneum and the status of the in situ graft when applicable. The follow-up imaging regimen is typically dictated by the clinical scenario, but a CT at 2 weeks, 3 months, 6 months, and then at 6- to 12-month intervals thereafter, is common. In the event that stable imaging is obtained over the first few CT scans, later imaging may not be warranted. Predictably, the morbidity and mortality rates associated with infected AAAs are significant with a 40% mortality rate reported in a recent publication.³⁰⁰

Aortoenteric Fistulae

An aortoenteric fistula is a communication between the aorta and the bowel. The duodenum is involved most commonly at the site where it crosses anterior to the aorta, but the communication can develop between almost any portion of the intestine. Primary aortic fistulae result when an aortic aneurysm erodes into the bowel and are distinctly rare with a reported incidence of 0.04% to 0.07% in autopsy series.³⁰¹ Debonnaire et al.³⁰² identified 18 primary aortoenteric fistulas through a survey of 196 Belgian surgeons and reported a mortality rate of 30%. Secondary aortic fistulae result from the erosion of a prosthetic aortic graft into the bowel; are significantly more common, with a reported incidence of 0.1% to 2.0% after aortic reconstruction.³⁰³ Notably, they can also occur after EVAR.³⁰⁴ The management of both primary and secondary aortic fistulae is the same.

The diagnosis of an aortoenteric fistula is often difficult and mandates a high index of suspicion. Patients usually present with gastrointestinal bleeding manifested as either hematemesis or melena. The initial episode of gastrointestinal bleeding is often self-limited and has been described as a “herald” bleed. The diagnosis of aortoenteric fistula should be foremost among the differential when a patient with a known aneurysm or prior aortic reconstruction presents with intestinal bleeding. Patients should undergo endoscopic evaluation of the upper and lower intestinal tract to determine the source of bleeding. It is imperative that the clinical suspicion of an aortoenteric fistula be communicated to the endoscopist to ensure that the third and fourth portions of the duodenum are adequately examined, which is not typically done during routine foregut endoscopy. The endoscopic findings of erosion, thrombus, active bleeding, or visible prosthetic graft in third or fourth portion of the duodenum are diagnostic of an aortoenteric fistula and mandate emergent treatment due to the risk of massive hemorrhage. Mild duodenitis and gastritis without frank erosion are frequently seen at the time of endoscopy and do not exclude the diagnosis of an aortoenteric fistula. Notably, the findings during upper endoscopy are normal in up to 30% of patients with a documented aortoenteric fistula.³⁰⁵ A CT should be performed if the results of endoscopy are inconclusive. The findings on CT that suggest an aortoenteric fistula include inflammation within the retroperitoneum, an anastomotic pseudoaneurysm, close approximation of the bowel and the prosthetic aortic graft or aneurysm, and loss of the normal tissue planes between the duodenum (or any other bowel segment) and the aorta or prosthetic graft. Occasionally, both endoscopy and CT are nondiagnostic despite the clinical suspicion of an aortoenteric fistula. Exploratory laparotomy is recommended in this setting for both diagnosis and treatment. Adherence of the bowel to the aorta at the time of the initial exploration suggests an aortoenteric fistula and mandates obtaining suitable proximal and distal control of the aorta, iliac vessels, or prosthetic

graft before further dissection. The diagnosis cannot be excluded until the bowel is entirely separated from the retroperitoneum and graft.

The treatment of an aortoenteric fistula requires repair of the defect in the gastrointestinal tract in addition to repair of the aneurysm or treatment of the infected prosthetic graft. Treatment of the gastrointestinal defect is usually straightforward and is based on standard surgical principles.³⁰⁶ After the fistula is disassembled, the edges of the bowel can be debrided and a primary closure performed. A limited bowel resection or enteral diversion may be necessary. The intraoperative and longer-term management of the aortic aneurysm or prosthetic graft is the same as that outlined above for infected aortic aneurysms. In situ replacement of the prosthetic graft or infrarenal aorta using autogenous femoral vein or cryopreserved aortic allograft, ligation of the infrarenal aorta with excision of the prosthetic graft and extra-anatomic bypass, or temporary in situ aortic replacement with staged extra-anatomic bypass and subsequent graft excision are all reasonable options. The decision algorithm is based upon the hemodynamic stability of the patient, their baseline physiologic state, and the anatomy and involvement of the aorta. In older/sicker patients, the most expeditious procedure is probably best, which is often in-line replacement of the infected graft with a Rifampin-soaked Dacron graft. If the patient stabilizes afterward, a planned graft excision with aortic stump ligation and extra-anatomic axillary–femoral–femoral bypass can be performed. Replacement of the infected graft using autogenous femoral vein (neo-aorto-iliac system [NAIS]) is reasonably well tolerated in younger/healthier patients, and may be a better option that obviates the risk of aortic stump blow-out. If the visceral segment is involved, ligation of the aorta may not be possible without sacrifice of the renal arteries, and replacement using cryo-preserved aortoiliac conduit, rifampin-soaked Dacron, or autogenous femoral vein may be the best options. In any case, these patients should be maintained on long-term antibiotics and undergo serial imaging studies, as outlined for infected aneurysm patients.

Venous Anomalies

Anomalies of the vena cava and renal veins are occasionally encountered at the time of aortic reconstruction. The common anomalies are related to the embryologic development of the iliac veins and vena cava. The four most clinically relevant anomalies include duplication of the inferior vena cava (0.2% to 3.0%), left-sided vena cava (0.2% to 0.5%), circumaortic left renal vein (1.5% to 8.7%), and retroaortic renal vein (1.2% to 2.4%).³⁰⁷ Patients with a duplicated inferior vena cava have large veins that run parallel to the infrarenal aorta and join together either anterior or posterior to the aorta at the level of the renal vein. In the case of a left-sided inferior vena cava, the cava runs parallel to the left side of the aorta, and the normally located right-sided vena cava is absent. The left-sided vena cava typically crosses the aorta at the level of the renal vein to become the suprarenal inferior vena cava, and the gonadal and adrenal veins on the right drain directly into the renal vein in a mirror image of the normal anatomy. The circumaortic left renal vein forms a collar of veins that surrounds the aorta at the normal level. In the case of a retroaortic left renal vein, a single vein runs posterior to the aorta at a slightly more caudal location. Notably, both duplication of the inferior vena cava and left-sided vena cava can be associated with other venous anomalies, including a circumaortic or retroaortic renal vein.

The diagnosis of the various venous anomalies can usually be made preoperatively on CT. Identification of the vena cava and left renal vein should be part of the mental checklist used when the preoperative CT scans are reviewed. The various anomalies may not become evident immediately in the operating room if missed on the preoperative imaging studies. A very prominent left renal vein at the usual location or slightly inferior is suggestive of a left-sided vena cava, whereas the absence of a left renal vein despite dissection along the anterior aspect of the aorta at the level of the SMA is suggestive of a retroaortic renal vein.

Open repair of an infrarenal AAA in a patient with a venous anomaly is essentially the same as the standard approach although additional care should be exercised to prevent inadvertent injury of the aberrant vein. Exposure of the infrarenal neck is more difficult in the presence of a duplicated or left-sided vena cava. However, sufficient exposure can usually be obtained by gentle dissection and mobilization of the venous structures. The presence of a duplicated or left-sided vena cava is a relative contraindication to the left retroperitoneal approach, but is not absolutely contraindicated. A circumaortic left renal collar or retroaortic left renal vein presents a potential hazard when the proximal aortic clamp is applied. A vertical aortic clamp is recommended and obviates the dissection on the posterior aspect of the aorta. Transecting the aorta may facilitate exposure of a retroaortic renal vein when significant bleeding is encountered.

Renal Anomalies

Congenital variations in the kidney anatomy may complicate the repair of an AAA. Specifically, aberrant kidney anatomy may complicate the dissection during open repair because they are frequently associated with multiple renal arteries, aberrant venous return, and abnormally positioned ureters. The various congenital anomalies of the upper urinary system have been classified in an attempt to standardize the approach for vascular surgeons.³⁰⁸ The anomalies have been broken down into abnormalities of position, including simple ectopia, and abnormalities of both form and fusion, including horseshoe kidney, crossed renal ectopia without fusion, and crossed renal ectopia with fusion. An ectopic kidney may be positioned anywhere from the pelvis to the thorax. Common forms of ectopic kidney include the pelvic kidney, located opposite the sacrum and below the aortic bifurcation; the lumbar kidney, located opposite the sacral promontory in the iliac fossa and anterior to the iliac vessels; the abdominal kidney, located above the iliac crest adjacent to the second lumbar vertebra; and the thoracic kidney, which can be located above the diaphragm in the posterior mediastinum. In a horseshoe kidney, two distinct renal masses are fused together by either a bridge of renal parenchyma or fibrous tissue; in the overwhelming majority, the lower poles are fused. In crossed renal ectopia, the kidney mass is located on the side opposite to its insertion in the bladder. Multiple configurations of crossed ectopia with and without fusion have been described.

The preoperative objective for the various renal anomalies is to image the renal mass adequately, delineate the course of the ureter, and establish the arterial and venous supply. The approach is simplified by the fact that most patients undergo abdominal/pelvic CT as part of the preoperative evaluation. The location and position of both the kidneys and ureters, like the position of the left renal vein, should be established as part of the review of every CT scan for patients with aneurysms. Formerly, it was recommended that patients with renal anomalies undergo preoperative arteriography to confirm the location and number of renal arteries. However, this information can now be obtained from the CT arteriogram, which is now part of the routine preoperative evaluation.

Patients with renal anomalies can safely undergo repair of an AAA using either an open or endovascular approach.^{309–311} However, the anomalies must of course be factored into the operative plan. The specific operative approach depends on the location of the renal mass, blood supply, course of the ureters, and presence of fusion. A left-sided retroperitoneal or transperitoneal approach with medial visceral rotation is the most helpful for open repair, particularly in patients with a horseshoe kidney. A standard transperitoneal approach with transection of the fused parenchyma can be used in patients with a horseshoe kidney although this may be associated with both significant bleeding and a urine leak and, therefore, is discouraged. The frequently encountered multiple renal arteries can be handled most expeditiously by using a Carrel patch technique, in which a cuff of aorta including the renal artery orifices is reimplanted into the aortic graft after completion of the proximal anastomosis. Endovascular repair is possible in many cases with the feasibility dictated by the location of the renal arteries in addition to the other standard anatomic considerations. Use of the endovascular approach may require covering at least one of the renal vessels and has been associated with loss of some renal parenchyma.³⁰⁹

Coexistent Renal or Visceral Artery Occlusive Disease

Coexistent renal or visceral artery occlusive disease is frequently found in patients undergoing AAA repair. The optimal management of patients with coexistent lesions remains unresolved. The options include repair of the aneurysm alone, simultaneous repair of the aneurysm and revascularization of the renal or visceral vessels, and staged repair, with either aneurysm repair or revascularization performed first. Furthermore, the specific treatment options include both open and endovascular alternatives for the aneurysm repair and visceral/renal revascularization (i.e., angioplasty/stent). The rapid expansion of the endovascular technologies has afforded effective, safe approaches that have replaced open surgical revascularization for both renal and visceral artery lesions to a great degree. Regardless, the optimal approach represents a balance between the indications for the procedure and the associated added risk.

Renal/visceral revascularization is mandatory at the time of open aneurysm repair if the affected vessels are involved in the aneurysm, as in a suprarenal aneurysm or a horseshoe kidney. More commonly, a lower pole or accessory renal artery may arise from the aneurysm. The decision to perform a concomitant revascularization with either reimplantation or a bypass graft in this setting depends on the size of the vessel and the quantity of kidney parenchyma perfused. Revascularization is recommended for larger vessels (>2 mm) that supply a significant portion of the renal mass. The presence of any accessory renal arteries should factor into the operative plan and the general feasibility

for endovascular repair. Covering small, accessory renal arteries has been reported to be safe, although it must be appreciated that this approach sacrifices some renal parenchyma.³¹²

Combined aneurysm repair with renal or visceral artery revascularization may be justified if the indications for renal or visceral artery revascularization are satisfied. The traditional indications for renal revascularization included poorly controlled hypertension in a patient with a significant renal artery stenosis and rapidly progressive renal insufficiency in a patient with adequate renal mass and bilateral renal artery stenosis. However, the antihypertensive agents have improved to the point that renal revascularization is currently reserved for patients with poor blood pressure control despite optimal medical therapy with at least three separate medications, including a diuretic.^{313,314} Endovascular treatment of the renal artery stenosis (when indicated) can be performed prior to open aneurysm repair or simultaneous with the endovascular approach. Although feasible, simultaneous open aneurysm repair and renal artery bypass is associated with a significant increase in the operative mortality rate relative to the aneurysm repair alone.^{315,316}

The traditional indications for mesenteric revascularization include symptoms of chronic mesenteric ischemia and critical stenosis of either the SMA alone or two of the three visceral vessels. Patients with chronic mesenteric ischemia and AAAs should have their visceral occlusive disease corrected prior to aneurysm repair when possible. Repairing the aneurysm first potentially increases the risk of developing acute mesenteric ischemia in the perioperative period, and performing concomitant mesenteric revascularization with AAA repair carries significant morbidity/mortality over and above that seen with open mesenteric revascularization alone.³¹⁷⁻³¹⁹ Endovascular treatment with stent placement is probably the optimal treatment for the visceral lesions in this setting because of its simplicity, despite the concerns about its longer-term durability.³²⁰⁻³²²

The optimal treatment for patients with aneurysms and *asymptomatic* renal or visceral artery lesions remains poorly defined. Natural history studies with the use of both arteriography³²³ and duplex scanning³²⁴ have suggested that significant renal artery stenoses are preocclusive lesions that may merit intervention. However, analysis of patients with asymptomatic renal artery stenosis who underwent aortic reconstruction found that the natural history of the renal artery lesions is fairly benign when untreated and is associated only with an increase in the antihypertensive requirements.³²⁵ Little is known about the natural history of asymptomatic mesenteric occlusive lesions. However, a small report has suggested that patients with asymptomatic severe mesenteric occlusive disease involving all three visceral vessels have a high incidence of bowel infarction.³²⁶ Ultimately, consideration should be given to mesenteric revascularization prior to aneurysm repair in patients with severe visceral artery occlusive disease due to the potential risk of mesenteric infarction at the time of aneurysm repair as noted above.

Additional Concurrent Intra-abdominal Disease

The finding of an AAA and an additional intra-abdominal process that may require operative repair is a frequent event. A second surgical problem may be identified as part of the preoperative evaluation or discovered at the time of the exploratory laparotomy during open aneurysm repair. Alternatively, an AAA may be identified during the surgical treatment of another problem. No algorithms have been defined for the management of such concurrent problems, and the overall approach certainly requires sound clinical judgment. Options include simultaneous performance of the necessary operations, or a staged operation with repair of the AAA as either the first or second procedure. The approach depends on the risk for aneurysm rupture, natural history of the second surgical problem, and potential for infection of the prosthetic graft during simultaneous repair. Notably, both the laparoscopic and endovascular approaches have impacted the approach to patients with combined problems due to their reduced morbidity and mortality facilitates a more rapid, definitive treatment.

The generic recommendation for patients with an AAA and an additional intra-abdominal surgical problem is that the most life-threatening problem be addressed first. The natural history of untreated AAA has been defined reasonably well and has been outlined extensively earlier in this chapter. It has been suggested that the risk for aneurysm rupture is increased after major intra-abdominal surgery and that it is potentially related to an increase in collagenase activity.³²⁷ However, this reported increased rupture risk is speculative and should not necessarily be factored into the decision algorithm. The management of concurrent colon cancer and AAA is a frequent treatment dilemma that provides an excellent illustration of the approach to these problems. Indeed, the reported incidence of colon cancer and an AAA occurring simultaneously ranges from 0.5% to 2.1%.²⁰⁵ The treatment principles suggested by Szilagyi et al.³²⁸ included the following: (a) aneurysm repair first in the presence of rupture; (b) colon resection first in the presence of hemorrhage, perforation, or obstruction; (c) aneurysm repair

first in the presence of a large aneurysm and a small colon cancer; (d) colon resection first in the presence of a large colon cancer and a small aneurysm.

Simultaneous AAA repair and cholecystectomy is probably safe for patients with cholelithiasis or evidence of chronic cholecystitis. The safety of these simultaneous procedures has been documented in several series, and the concerns about an increased incidence of aortic graft infection have not been substantiated.³²⁹ Advocates of the simultaneous approach justify the cholecystectomy by the potential requirement for a cholecystectomy in the future and the morbidity and mortality associated cholecystitis after aneurysm repair.³²⁹ Although a consensus is not found in the literature, simultaneous AAA repair and cholecystectomy are recommended only if evidence of chronic cholecystitis or multiple small stones is present. Regardless, the cholecystectomy and other simultaneous procedures should not be performed until after the aneurysm repair is completed and the retroperitoneum closed in an attempt to reduce the hypothetical risk for graft infection.

The safety and utility of other simultaneous procedures remain poorly defined although a wide range of procedures have been combined with open aneurysm repair.^{202–205} The repair of ventral hernias is often mandatory to achieve a tension-free abdominal closure and should be viewed more as an extension of the aneurysm repair than as a simultaneous procedure. Inguinal hernias may be repaired at the time of aneurysm repair, but it is uncertain whether the small risk associated with a subsequent procedure at a later date offsets the obligatory additional time for the simultaneous repair. Appendectomy³³⁰ and small-bowel excision for Meckel's diverticulum³²⁹ have been reported to be safe when performed concomitantly with aneurysmectomy although the natural history of the associated underlying problems in the usual age group of patients undergoing AAA repair is relatively benign.

Chapter 97

Lower Extremity Aneurysms

Amy B. Reed

Key Points

- 1 Femoral and popliteal aneurysms are often incidental findings on routine physical examination, but are potentially limb threatening and frequently associated with life-threatening abdominal aortic aneurysms.
 - 2 Femoral artery aneurysms are the most common peripheral aneurysm *if* both true and false aneurysms are considered together.
 - 3 Anastomotic aneurysms result from a disrupted suture line between a graft and the host artery.
 - 4 Pseudoaneurysms after percutaneous intervention result from failed hemostasis.
 - 5 Popliteal artery aneurysms often develop limb-threatening complications if not treated electively.
 - 6 Thrombolytic therapy is a useful adjuvant in patients presenting with acute limb ischemia secondary to occlusion of a popliteal artery aneurysm and the outflow arteries.
-

PERIPHERAL ANEURYSMS

1 Popliteal artery aneurysms are the most frequently encountered peripheral aneurysm. Their significance comes from their potential for limb-threatening complications, rather than rupture, and their association with life-threatening abdominal aortic aneurysms. True femoral artery aneurysms are rare, with iatrogenic and anastomotic pseudoaneurysms being more common.

Incidence

While the exact incidence of femoral and popliteal aneurysms is difficult to determine, the number being recognized is increasing. An aging population, increased arterial trauma, more common use of invasive therapies for vascular disease, and increased use of imaging modalities all contribute to the rise in number of peripheral aneurysms being diagnosed. In a screening study of men between the ages of 65 and 74 years, abdominal aortic aneurysms were identified in 4.9% of patients.¹ In patients with abdominal aortic aneurysms, 6.8% had femoral artery aneurysms and 9.6% had popliteal artery aneurysms.² Screening of men between the ages of 65 and 80 years identified popliteal artery aneurysms in 1%.³

An increasing number of false aneurysms – “pseudoaneurysms” – are occurring coincident with the increased use of catheter-based diagnostic and therapeutic interventions in addition to lower extremity bypass surgery. Pseudoaneurysms can be iatrogenic, infectious, or traumatic in nature and are identified by their lack of involvement of all three vessel wall layers as is typically seen in true aneurysms. The incidence of pseudoaneurysm after diagnostic procedures is approximately 0.3% – slightly higher at 1.5% after therapeutic procedures, in general due to use of larger sheaths.⁴ False aneurysms can also arise from trauma during surgery, such as orthopedic procedures. Femoral pseudoaneurysms develop after 0.08% of total hip arthroplasties, and popliteal aneurysms arise following 0.17% of total knee arthroplasties.⁵

Degenerative (often called atherosclerotic) femoral and popliteal artery aneurysms are encountered far more frequently in men than women. The male to female ratio in patients with femoral and popliteal aneurysms is about 30:1.^{6–8} This predilection for men is markedly different from aortic aneurysms where male to female patient ratio is approximately 4:1.²

Pathogenesis

The cause of femoral and popliteal aneurysms has changed significantly since they were first recognized centuries ago. Once primarily mycotic or syphilitic in origin, most true aneurysms in the 21st century

have a degenerative cause commonly called *atherosclerotic aneurysms*, whereas false aneurysms usually follow surgery or trauma. True tibial artery aneurysms are rare.

The cause of degenerative aneurysms of the femoral and popliteal vessels is not clear. One factor believed to contribute to aneurysm formation is turbulent flow beyond a relative stenosis resulting in poststenotic dilatation beyond the inguinal ligament at the groin or beyond the tendinous hiatus of the adductor magnus or the arcuate popliteal ligament and the heads of the gastrocnemius muscle at the popliteal level. Arterial wall fatigue resulting from vibration and turbulence proximal to a major branching or caused by stress during hip and knee flexion may also contribute to aneurysm formation.

The frequent occurrence of multiple peripheral aneurysms in the same patient suggests a systemic abnormality in the arterial wall, which promotes aneurysmal degeneration at locations where hemodynamic or mechanical factors put unusual stress on the arterial wall. The multiple factors that contribute to aneurysmal degeneration and are felt to contribute to degenerative femoral and popliteal aneurysms, as well as aortic aneurysms. The presence of an inflammatory infiltrate has been noted in the wall of femoral and popliteal aneurysms, similar to aortic aneurysms.⁹ The exact role of this inflammatory process, with potential release of reactive oxygen species and matrix metalloproteinases, is unknown. Apoptosis of smooth muscle cells may also play a role in the formation of aneurysms by limiting the ability of the arterial wall to respond to the degenerative process.¹⁰ These factors, however, do not explain the male predilection for femoral and popliteal aneurysm formation. X-linked genetic abnormalities for aneurysm formation in popliteal artery aneurysms have not been noted in humans.

Clinical Manifestations

Femoral and popliteal aneurysms are often asymptomatic, being detected on routine physical examination by a bounding, expansile pulse. Both femoral and popliteal artery aneurysms, however, may be accompanied by symptoms of local fullness, pain caused by pressure on the adjacent nerve, limb edema, and venous distention or thrombosis caused by compression of the adjacent vein. Patients may also present with lower extremity ischemia with intermittent claudication, rest pain, or gangrene secondary to complications of a femoral or popliteal aneurysm including thrombosis or distal embolization. Because the natural history and complication rate in femoral and popliteal aneurysms differ, they are considered separately here.

FEMORAL ARTERY ANEURYSMS

2 Femoral artery aneurysms are the most common peripheral aneurysm if both true and false aneurysms are considered together, with the vast majority being false aneurysms. Their clinical importance rests in the fact that they are limb-threatening lesions and can jeopardize the viability of the leg if thrombosis, embolization, or rupture occurs. The vast majority of true aneurysms are degenerative lesions commonly called *atherosclerotic aneurysms*, whereas false aneurysms include anastomotic, traumatic, and mycotic lesions. Rarely, femoral aneurysms develop secondary to connective tissue disorders. The femoral region is the most common site for both anastomotic aneurysms and mycotic aneurysms associated with trauma; so the presentation and surgical repair of these lesions are discussed.

Degenerative (Atherosclerotic) Aneurysms

Incidence

The exact incidence of degenerative (atherosclerotic) common femoral artery aneurysms in the general population remains undefined. They are found in 6.8% of all patients with abdominal aortic aneurysms, and 85% of patients with femoral artery aneurysms have abdominal aortic aneurysms.^{2,6}

Pattern of Disease

Femoral aneurysms most frequently affect the common femoral artery. They may be classified as *type I*, those limited to the common femoral artery, or *type II*, those involving the orifice of the profunda femoris artery.¹¹ Type I and type II aneurysms occur with nearly equal frequency. This classification becomes important in reference to vascular reconstructive procedures, with type II aneurysms requiring more complex reconstructions to ensure continued patency of both the superficial and profunda femoris arteries. Isolated lesions of the profunda femoris artery are rare (2% of femoral artery aneurysms), and are prone to rupture because they are difficult to diagnose at the asymptomatic stage. Isolated superficial femoral artery aneurysms are also uncommon, but one-third of patients present with rupture

and one-quarter with thrombosis.¹²

Femoral artery aneurysms can be limb-threatening lesions and are frequently associated with limb-threatening popliteal aneurysms and life-threatening abdominal aortic aneurysms. Multiple aneurysms are common in patients with femoral artery aneurysms. In a series of 100 patients with degenerative femoral artery aneurysms seen at a single institution, 72% of patients had bilateral femoral artery aneurysms.⁶ In addition, aortoiliac aneurysms were detected in 85% of patients, thoracic aortic aneurysms in 6%, and popliteal aneurysms in 44%, of which 55% were bilateral.

Clinical Manifestations

The typical patient with a degenerative femoral artery aneurysm is a male in his sixties or seventies with the usual risk factors for atherosclerosis. Of these patients, 86% are cigarette smokers, 36% have hypertension, and 14% have diabetes mellitus.⁶ Associated cardiovascular disease is common, with clinical manifestations of coronary artery disease and cerebrovascular disease present in 34% and 7%, respectively.

The clinical manifestations of femoral artery aneurysms cover the spectrum from asymptomatic to severe ischemia of the lower extremity. Although 40% of patients are asymptomatic at the time of diagnosis, the majority present with local symptoms or complaints of lower extremity ischemia.⁶ Local pain or observation of a groin mass is the only complaint in 18% of patients. Lower extremity venous disease is present in 8%, being attributable to venous obstruction by the femoral artery aneurysm in 4%; but venous obstruction is rarely the sole sign of an aneurysm. Lower extremity ischemic symptoms of claudication, rest pain, or gangrene are present in 42% of patients and often lead to the diagnosis of the femoral artery aneurysm.

As with aneurysms in other locations, femoral artery aneurysms may be complicated by embolization, thrombosis, or rarely rupture. Peripheral embolization may be identified incidentally on angiography or produce signs as mild as spotty discoloration of the toes to as severe as peripheral gangrene. Although embolization is reported in about 10% of aneurysms, the femoral artery aneurysm is not necessarily the source of these emboli because many patients have a concomitant popliteal aneurysm.⁶ In larger clinical series, 1% to 16% of patients with degenerative femoral artery aneurysms present with an acute thrombosis, whereas 1% to 16% have a chronically thrombosed lesion.^{6,10} Rupture is reported in 1% to 14% of aneurysms.^{6,11}

Natural History

The natural history of degenerative femoral artery aneurysms is poorly defined. Most publications have reviewed aneurysms that were treated surgically. A small asymptomatic femoral artery aneurysm does not appear to pose the same threat to the limb as does a popliteal artery aneurysm. In a series of 236 patients with atherosclerotic femoral artery aneurysms, serious limb-threatening complications were documented in only 3% of the 236 aneurysms.⁷

Diagnosis

In most cases the diagnosis of femoral artery aneurysm is suspected by the finding of a pulsatile groin mass on routine physical examination or during evaluation for vascular disease. If the femoral artery aneurysm is small or thrombosed, detection on physical examination may be difficult. Although a radiograph of the region may occasionally demonstrate the calcified rim of the aneurysm, only ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) can reliably establish the diagnosis of the femoral aneurysm. In addition, these modalities are useful in accurately defining the size of the lesion and evaluating associated aneurysmal disease in the distal aorta and popliteal regions. These findings are particularly important because life-threatening abdominal aortic aneurysms are missed on physical examination in 50% of patients with multiple aneurysms.¹³ The diagnostic accuracy of arteriography is limited because it demonstrates only the residual lumen and an aneurysm filled with smooth mural thrombus may be missed, but the definition of the vascular anatomy of the lower extremity provided by angiography is helpful in planning the appropriate operative procedure (Fig. 97-1).

Treatment

Operative treatment of femoral aneurysms is indicated for those causing local symptoms and presenting with limb-threatening complications. Asymptomatic aneurysms greater than 3.5 cm in diameter should also be repaired unless the patient is a prohibitive risk for operative intervention. In patients with small, asymptomatic aneurysms, observation may be appropriate, particularly in a patient with multiple

medical problems who would be at high risk for surgery. When nonoperative management is selected, the size of the aneurysm should be documented by ultrasonography. The patient should be followed at regular intervals with ultrasound scans and careful examination for occult complications. Operative treatment should be undertaken without undue delay if the femoral aneurysm enlarges, produces symptoms, or is complicated by embolization, thrombosis, or rupture.

Figure 97-1. Arteriogram demonstrating bilateral femoral artery aneurysms that extend into the superficial femoral arteries. Unlike many patients with femoral artery aneurysms, this patient did not have an associated aortic aneurysm or popliteal aneurysms.

Surgical Strategy. The operative approach is individualized based on associated aneurysmal disease. In patients with multiple asymptomatic aneurysms, treatment is staged. The life-threatening aortic lesions are treated before limb-threatening femoropopliteal lesions. Femoral artery aneurysms are addressed after popliteal lesions unless the femoral aneurysm is repaired in combination with treatment of the aortic or popliteal aneurysm. If an aortofemoral bypass is necessary, the femoral aneurysm should be treated at the same time, to avoid later anastomotic aneurysm formation. The graft limb can be anastomosed into an interposition graft that has replaced the femoral aneurysm. Similarly, if a stent graft is placed for treatment of an abdominal aortic aneurysm in a patient with femoral artery aneurysms, the aneurysm should be repaired with an interposition graft. In patients with severe lower extremity ischemia, the femoral aneurysm is treated with an interposition graft, from which the proximal anastomosis of the required femoropopliteal or femorotibial bypass is based.

Technique. The operative procedure for treatment of an isolated femoral artery aneurysm is determined by aneurysmal involvement of the superficial and deep femoral arteries as well as by the existence of lower extremity occlusive disease. The femoral artery aneurysm is usually approached through a longitudinal groin incision. When addressing an unusually large aneurysm or a ruptured aneurysm, however, initial proximal control of the external iliac artery through a retroperitoneal approach is advisable. After proximal and distal arterial control is obtained, the aneurysm sac is opened and the atheromatous debris removed. Small aneurysms may be excised, but routine excision of large aneurysms is not recommended as these lesions can often be adherent to the adjacent vein and nerve. For type I aneurysms, the preferred treatment is reconstruction with an interposition graft of Dacron or expanded polytetrafluoroethylene with the proximal anastomosis at the distal external iliac artery or proximal common femoral artery and the distal anastomosis at the femoral bifurcation.

For type II aneurysms with patent superficial and profunda femoris arteries, an interposition graft to the profunda femoris artery with reimplantation of the superficial femoral artery is one standard configuration. If the superficial femoral artery is chronically occluded and the patient has minimal symptoms, an interposition graft to the profunda femoris artery alone is sufficient. If the patient has severe lower extremity ischemia, this is typically followed by a standard distal reconstruction. If recent emboli or in situ thrombosis have occluded the outflow tract, percutaneous mechanical thromboembolectomy or catheter-directed thrombolytic therapy is useful before open arterial reconstruction is undertaken.

Results

Results of surgical therapy depend upon the patency of the distal vasculature. More than 80% of asymptomatic patients have excellent long-term results, whereas 68% of those presenting with lower extremity ischemia achieve satisfactory long-term outcomes.⁶

Anastomotic Pseudoaneurysms

Incidence

3 Anastomotic pseudoaneurysms result from a disrupted suture line between a graft and the host artery. The incidence varies with the location of the anastomosis and the type of graft that is used. Involvement of the femoral artery accounts for nearly 80% of these lesions, and 3% of all femoral anastomoses or 6% of femoral anastomoses after aortofemoral bypass develop this complication compared with 0.2% of aortic anastomoses.^{14,15} Patient factors that are associated with increased likelihood of developing a femoral anastomotic aneurysm after aortofemoral bypass include chronic obstructive pulmonary disease, current smoking, and postoperative groin wound infection.¹⁶ After infrainguinal bypass procedures, the incidence is higher with prosthetic grafts than autogenous vein grafts with 6% of femoral anastomoses developing aneurysms when Dacron is used compared with 0.9% when a vein graft is placed.¹⁴ Anastomotic pseudoaneurysms are a late complication of bypass procedures; the mean interval from primary procedure to recognition is more than 6 years.^{17,18}

Pathogenesis

Several factors contributing to anastomotic pseudoaneurysm formation have been identified including weakness of the arterial wall, the type of graft material and suture utilized, the presence of infection, the method of construction of the anastomosis, and the stress on the suture line from hypertension, leg motion, or excess tension on the graft limb.^{14,17,18} Progressive degeneration of the recipient artery accounts for most anastomotic pseudoaneurysms, and an increased incidence has been noted following endarterectomy of the artery at the anastomosis. False aneurysms occur less frequently with saphenous vein grafts than synthetic vascular grafts, a reflection of more complete healing of autogenous tissue. With the use of monofilament synthetic suture, anastomotic pseudoaneurysms rarely result from a loss of suture integrity, although occasionally a broken suture is a factor in pseudoaneurysm formation. Although most anastomotic aneurysms are not accompanied by overt graft infection, occult infections with coagulase-negative *Staphylococcus* species may be an important factor in development of anastomotic aneurysms.¹⁸ A higher incidence is noted in patients with wound healing complications, and the use of anticoagulants may increase such complications.

Clinical Manifestations

Femoral anastomotic pseudoaneurysms usually present as a pulsatile groin mass, which may or may not be accompanied by pain, redness, or symptoms of venous obstruction. Acute complications include hemorrhage, embolization, and occlusion. The latter may cause lower extremity ischemia with claudication, rest pain, or gangrene.

Diagnosis

The diagnosis of a false aneurysm is usually made on physical examination by the presence of a pulsatile groin mass in a patient who has undergone a femoral arterial reconstructive procedure. The differential diagnosis includes nonpulsatile groin masses, such as hernia, lymphocele, or abscess, through which pulsation is transmitted from an underlying normal femoral artery. Diagnosis of an anastomotic disruption in one region should raise suspicion of other anastomotic pseudoaneurysms as multiple lesions are found in at least 30% of patients.¹⁷ The presence of multiple anastomotic pseudoaneurysms suggests infection. Evaluation of an anastomotic aneurysm includes ultrasonography or CT of all anastomoses of the graft. Angiography done prior to repair of the anastomotic aneurysm is helpful in defining the proximal and distal arterial anatomy (Fig. 97-2).

Treatment

Because of the progressive nature of anastomotic pseudoaneurysms, surgical treatment is generally undertaken for all lesions >2 cm except those in high-risk patients. Principles of surgical therapy are those of primary aneurysms: obtain proximal and distal control and replace the aneurysmal segment. Securing proximal control often requires dividing the inguinal ligament to isolate the graft limb. Distal control is most easily obtained using intraluminal balloon catheters. If intrinsic arterial disease requires extension of the graft distally on the profunda femoris or superficial femoral artery, these arteries can

be identified by dissection through unscarred tissue distal to the previous exposure. After débridement of the degenerated artery, an interposition graft is placed between the prosthetic graft limb and the healthy native artery. Cultures of the graft and vessel wall are essential to exclude infection as an etiologic factor in the development of the anastomotic aneurysm. If infection is obvious at the time of surgery, the approach is the same as that of any infected graft with removal of infected prosthetic material and reestablishment of blood flow, if necessary, with a bypass through an uninfected tissue route, such as an obturator, lateral femoral, or axillofemoral bypass.

Figure 97-2. Arteriogram demonstrating bilateral femoral anastomotic aneurysms after an aortofemoral bypass and a left femoropopliteal bypass.

Results

Results of elective operations on uncomplicated anastomotic aneurysms are excellent with 2% operative mortality, 97.5% graft patency at 2 years, and 2% amputation within 2 years of surgery.¹⁷ Recurrence is reported in less than 16% of cases.^{14,15} Patients presenting with aneurysms complicated by hemorrhage, occlusion, or embolization have significantly increased operative morbidity and mortality.

Femoral Pseudoaneurysms

Incidence

The femoral artery is the preferred site for percutaneous access for both diagnostic and therapeutic angiography including endovascular grafts. In recent years, diagnostic studies for coronary and peripheral artery occlusive disease have increased as have the subsequent endovascular interventions, which have resulted in an increased number of femoral pseudoaneurysms. Because interventional techniques often require prolonged arterial cannulation, large-bore sheaths, and anticoagulation, they are accompanied by a higher rate of arterial complications than are diagnostic studies. Review of recent experience shows that pseudoaneurysms form after about 0.3% of diagnostic catheterizations and about 1.5% of catheter-based therapeutic procedures.^{4,19} The use of percutaneous closure devices decreases the risk of developing a pseudoaneurysm at the arterial access site for an interventional procedure by a factor of 10 to an incidence of about 0.1%.^{20,21}

Pathogenesis

4 Pseudoaneurysms from iatrogenic catheter trauma are classically defined as collections of blood in continuity with the arterial system that is not enclosed by all three layers of the arterial wall. These lesions form because of failed hemostasis at the arterial wall defect created by sheath insertion. Normally, hemostasis, aided by direct focal application of pressure or hemostatic devices, seals the defect promptly, and the arterial wall repairs itself. When hemostasis is not successfully obtained, blood under arterial pressure leaks from the artery, dissects surrounding tissue planes, and forms what is perceived on physical examination to be a pulsatile mass. The gross findings at surgery are a blood-

filled cavity surrounded by a capsule. Like all pseudoaneurysms, these lesions can cause symptoms by rupture or compression of surrounding structures.

Diagnosis

The diagnosis of femoral pseudoaneurysm is suspected when a pulsatile groin mass is noted after arterial catheterization. The differential diagnosis includes hematoma, lymphadenopathy, and abscess. Arterial duplex scanning or CT is typically used to establish the diagnosis, differentiate pseudoaneurysm from hematoma, and aid in defining the communication between the mass and the arterial lumen. Color-flow duplex scanning is the diagnostic test of choice, providing accurate diagnosis, localization, and sizing of the false aneurysms.

Natural History

Color-flow duplex scanning has been used to define the incidence and natural history of pseudoaneurysms after percutaneous transluminal coronary angioplasty.²¹ Many pseudoaneurysms will thrombose spontaneously within 4 weeks; however, this is less likely to occur in anticoagulated patients and those with pseudoaneurysms more than 2.0 cm in diameter. About 30% of patients with pseudoaneurysms will require intervention.²²

Algorithm 97-1. Management of femoral pseudoaneurysm.

Treatment

Therapy of femoral pseudoaneurysms is influenced by aneurysm size and symptoms, and whether the patient requires continuous anticoagulation (Algorithm 97-1). Surgical therapy is mandatory for all pseudoaneurysms that are acutely expanding, compressing adjacent nerves, or compromising the overlying skin. Proximal and distal arterial control is obtained, and the arterial defect is repaired directly, rarely requiring placement of more than one or two sutures.

An excellent alternative to a surgical approach, when urgent evacuation of the hematoma and arterial repair is not required, is the use of ultrasound-directed compression therapy or thrombin injection into the false aneurysm. The pseudoaneurysm is identified with a color-flow ultrasound probe, and then compressed with the scan head.²³ Real-time observation of flow in the underlying artery allows compression of the pseudoaneurysm while maintaining flow in the native vessel to prevent arterial occlusion. Pseudoaneurysm thrombosis is documented by absence of flow signals on release of scan-head pressure in the case of compression therapy. While effective, this can often be quite uncomfortable for the patient and take upward of 30 minutes of compression by the vascular technologist.

Another nonoperative treatment option of femoral pseudoaneurysms is percutaneous ultrasound-guided injection of 0.5 to 1.0 mL thrombin (1,000 U/mL) into the pseudoaneurysm away from the neck of the aneurysm.^{24–26} Thrombin injection avoids the discomfort of prolonged compression and is effective in anticoagulated patients. Continuous ultrasonographic imaging is used to monitor thrombosis

of the pseudoaneurysm.

Results

Ultrasound-guided compression therapy for femoral pseudoaneurysms results in thrombosis in 80% to 90% of cases. Initial success rate is similar in patients who are anticoagulated and in those who are not, though long-term success appears to be better in patients not receiving anticoagulant therapy. In one of the largest series of pseudoaneurysms treated with ultrasound-guided compression, thrombosis was achieved in 86% of anticoagulated patients, and in 98% of those not anticoagulated, with a 20% recurrence rate in less than 24 hours in anticoagulated patients.²⁷ Success using this therapeutic modality requires a knowledgeable ultrasonographer and meticulous postcompression follow-up.

Thrombin injection to induce thrombosis of pseudoaneurysms is successful in 94% to 98% of patients with thrombosis occurring in less than 1 minute.²⁴⁻²⁶ This technique can be complicated by arterial thrombosis if an excessive volume of thrombin is used and may not be appropriate for pseudoaneurysms with large necks. Remote thromboembolic events are rare and probably are not a result of a systemic effect of the thrombin. Allergic reactions to bovine thrombin occasionally occur. Large pseudoaneurysms, greater than 8 cm in diameter, and an associated arteriovenous fistula (AVF) are predictors of failure with thrombin injection.²⁸

Mycotic Aneurysms

The term *mycotic aneurysm* is currently used to refer to any infected aneurysm. Mycotic aneurysms today are often a complication of parental drug abuse, but can follow arterial trauma of any form, including invasive diagnostic and therapeutic procedures. In the past, septic emboli from bacterial endocarditis were a major cause of mycotic aneurysmal degeneration, but this is less common today. With the advent of antibiotics, aneurysms secondary to syphilis or tuberculosis are rare. With the change in cause, the location of mycotic aneurysms has shifted from central to peripheral arteries with the femoral artery being the most common site.^{29,30} The importance of mycotic aneurysms comes from their propensity to rupture.

Pathogenesis

The pathogenesis of mycotic aneurysms can be divided into four major categories, although other less common causes also exist.²⁹ First, septic emboli from bacterial endocarditis may lodge in normal arteries, causing infection that weakens the arterial wall, resulting in aneurysm formation. These lesions are often multiple. Second, during an episode of bacteremia, microorganisms may lodge in a pre-existing atherosclerotic plaque or aneurysm and begin to multiply with the same result. A third cause of mycotic aneurysms is the contiguous spread of bacteria from a local abscess. The inflammatory process destroys the arterial wall, causing pseudoaneurysm formation. Finally, trauma to the artery with concomitant contamination may result in formation of an infected pseudoaneurysm. This mechanism of mycotic aneurysm formation is being seen more frequently, coincident with the increased use of catheter-based procedures. Bacteria may be introduced concomitantly with needle puncture or by migration during prolonged arterial catheterization. Mycotic aneurysms accompanying drug abuse may be secondary to direct contamination of the arterial wall, or they may result from destruction of the vessel wall by a local abscess.

The bacteriology of arterial infections depends upon the cause of the lesion. Aneurysms secondary to bacterial endocarditis grew *Pneumococcus*, *Streptococcus*, and *Enterococcus* species most frequently in the past; but recently *Staphylococci*, *Salmonella*, *Escherichia coli*, and *Proteus* organisms also have been cultured.²⁹ *Staphylococcus aureus* is the most common pathogen in mycotic femoral artery aneurysms secondary to trauma and drug abuse, occurring in more than 65% of cases.³¹ In this population, at least 50% of the *S. aureus* organisms are resistant to methicillin.

Clinical Manifestations

The typical patient with a mycotic femoral aneurysm presents with a history of chills and fever, and a tender, enlarging, pulsatile groin mass. The patient may have a history of intravenous drug use, recent arterial catheterization, penetrating trauma, or bacterial endocarditis. Local signs of infection, including tenderness, erythema, and warmth are noted on physical examination. Lower extremity edema may occur secondary to venous or lymphatic obstruction. Petechial skin lesions, splinter hemorrhages, cutaneous abscesses, and septic arthritis may occur as a result of emboli originating from a mycotic aneurysm. A “sentinel bleed” may occur and signals impending rupture and life-threatening

hemorrhage. Emergency surgery is indicated.

Diagnosis

The diagnosis of a mycotic aneurysm is usually straightforward, but distinguishing an abscess adjacent to the femoral artery from a femoral mycotic aneurysm may be difficult. In the patient with a pulsatile groin mass, laboratory findings including a leukocytosis, elevated erythrocyte sedimentation rate, and positive blood cultures are suggestive, but not specific, for a mycotic aneurysm. Multiple blood cultures or downstream arterial blood cultures may be necessary to yield positive results. Ultrasonography and CT angiography are helpful in establishing the diagnosis of an aneurysm (Fig. 97-3), but lack precision in distinguishing infected from bland aneurysms. The diagnosis of a mycotic aneurysm is confirmed at operation by demonstration of organisms on Gram stain or by positive cultures of the aneurysm wall.

Treatment

Mycotic aneurysms represent a serious life- and limb-threatening disease because their natural history is one of expansion and rupture. Therefore, mycotic aneurysms should be addressed surgically. The goal of treatment is eradication of the infection by excision of the aneurysm and débridement of adjacent infected tissue as well as by long-term antibiotic therapy. Second, adequate distal circulation must be restored. Before operative intervention is performed, the patient is started on antibiotics that are modified based on sensitivity testing of intraoperative cultures. Stent grafts have been used in selected cases of mycotic aneurysms when other approaches were not feasible; however, concern about latent infection of the stent graft oftentimes renders this more of a bridging technique than a long-term solution.

Figure 97-3. Computed tomography scan of an infected femoral anastomotic aneurysm that was diagnosed 5 years after aortofemoral graft placement.

The complexity of the operative procedure varies with the location and extent of the mycotic aneurysm. Although a direct approach to the femoral artery may be taken, a retroperitoneal exposure of the distal external iliac artery for proximal control is sometimes preferred for large or proximal femoral lesions to avoid excessive hemorrhage. When an infected femoral artery aneurysm is confined to only one arterial segment (common, superficial, or deep femoral artery), the aneurysm is excised and the proximal and distal arteries are ligated in emergent situations. In these cases in which an isolated arterial segment is ligated, severe ischemia resulting in amputation is unusual. In more than 50% of cases, however, the mycotic aneurysm involves the femoral artery bifurcation, and treatment requires resection of the femoral bifurcation and débridement to healthy arterial wall. The distal external iliac or proximal common femoral artery, as well as the superficial and deep femoral arteries, are oversewn with nonabsorbable monofilament suture. This results in significant ischemia in most patients, but with the patient heparinized, symptoms gradually improve as collateral circulation increases. The majority of patients will not need revascularization for limb salvage,³¹ but up to one-third of patients will have limb-threatening ischemia.³² In patients in whom sepsis can be adequately controlled at the initial procedure, aggressive débridement may be followed by immediate revascularization using autogenous saphenous vein graft as the conduit and covering the graft with a sartorius muscle flap.³² Another option is to observe patients for 24 hours after arterial ligation and selectively revascularize only those

patients in whom limb-threatening ischemia persists. Use of prosthetic material is avoided because of the high incidence of early and late septic complications, though can occasionally be necessary through uninfected tissue planes such as the obturator or lateral femoral route. Antibiotics are begun preoperatively and continued for at least 6 weeks postoperatively.

POPLITEAL ARTERY ANEURYSMS

5 Popliteal aneurysms are limb-threatening lesions, the vast majority of which are degenerative in etiology. Occasionally, anastomotic or traumatic popliteal aneurysms, and rarely mycotic aneurysms, are encountered in contemporary clinical practice. The remainder of this section addresses only popliteal aneurysms that are degenerative in etiology.

Incidence

Popliteal artery aneurysms are the most common degenerative true peripheral aneurysm. They occur slightly more frequently than femoral artery lesions; however, popliteal aneurysms are relatively unusual compared to abdominal aortic aneurysms. Aortic aneurysms are diagnosed with about 10 times the frequency of popliteal aneurysms.^{33,34}

Pattern of Disease

Like patients with femoral artery aneurysms, multiple aneurysms occur frequently in patients with popliteal aneurysms. About 60% to 70% of patients have bilateral popliteal aneurysms, and 55% have extrapopliteal aneurysms.^{35,36} Abdominal aortic aneurysms are encountered in 40% to 50%, and are particularly common in patients with bilateral popliteal aneurysms, of whom about 70% have aortic aneurysms.³⁵⁻³⁷ Femoral artery aneurysms occur in nearly 40% of patients.^{36,37} The importance of this multiplicity of aneurysms is that they may be missed on physical examination. Therefore, their presence must be determined by other studies, such as ultrasonography or CT, so that potentially life-threatening abdominal aortic aneurysms and other limb-threatening lesions are identified and managed appropriately. Even when popliteal aneurysms are initially asymptomatic, patients will develop symptoms at a mean rate of 14% per year, and one-third will develop complications requiring emergent intervention within 5 years, resulting in poorer outcomes for both life and limb.^{38,39}

Clinical Manifestations

The typical patient with a popliteal aneurysm is a male in his 60s or 70s with the usual risk factors for atherosclerosis. Of patients with popliteal aneurysms, 50% to 75% are smokers, 40% to 60% have hypertension, and about 15% have diabetes mellitus.^{35-37,40} Other manifestations of cardiovascular disease are also common, with 10% of patients having manifestations of cerebrovascular disease and more than 40% having evidence of significant cardiac disease.³⁷

The clinical manifestations of popliteal artery aneurysms range from an asymptomatic pulsatile mass to severe lower extremity ischemia. About 40% of patients are asymptomatic at diagnosis.⁷ More than 50% of patients present with symptoms of limb ischemia, usually claudication, but the ischemia may be more advanced and manifested as rest pain or gangrene. Local symptoms, including sensation of a mass, local pain, and leg swelling or phlebitis secondary to compression of the adjacent vein, account for the remainder of symptoms. A popliteal artery aneurysm may be complicated by thrombosis, embolization, or rarely rupture. Thrombosis is reported in approximately 40% of patients,³⁶ and embolization occurs in about 25% of cases.³⁶ Some patients present with classic “blue toe syndrome,” but more commonly, repeated episodes of embolization occlude the outflow vessels and result in thrombosis of the aneurysm. Rupture occurs in fewer than 5% of popliteal aneurysms;^{35,36} and in these cases, the hemorrhage is usually confined to the popliteal space, thus permitting surgical intervention and arterial reconstruction in a timely fashion.

Natural History

The natural history of popliteal aneurysms is not well defined because most series are composed primarily of aneurysms that have been treated surgically. In a review of 29 reports in the English literature published between 1980 and 1994, subgroups of patients were identified whose aneurysms had been observed.⁷ A mean of 35% of patients with conservative follow-up developed ischemic complications, and 25% of these required amputation even with modern therapy. Thus, a significant

percentage of popliteal aneurysms will develop a complication if left untreated, and although this is not synonymous with limb loss, the amputation rate is high.

Figure 97-4. Computed tomography of large right popliteal aneurysm with significant laminar thrombus present.

Diagnosis

The diagnosis of popliteal aneurysm is usually first suspected on physical examination. Palpation of the popliteal space with the knee flexed reveals a pulsatile mass in approximately two-thirds of patients. Small aneurysms may not be palpable on physical examination, and if thrombosis has occurred the mass may be nonpulsatile. Radiographs of the knee demonstrating a calcified arterial wall occasionally suggest the diagnosis of a popliteal artery aneurysm, but it must be confirmed by duplex ultrasonography, CT ([Fig. 97-4](#)), or MRI. These diagnostic modalities can establish diagnosis of popliteal artery aneurysms and exclude other entities that could be responsible for a nonpulsatile popliteal fossa mass (tumor or Baker cyst). Ultrasonography, CT, or MRI is also useful in the detection of associated aneurysms, particularly abdominal aortic and femoral artery aneurysms. Angiography can be misleading in the diagnosis of aneurysms because intraluminal thrombus may obscure the true size of the vessel ([Fig. 97-5](#)); however, it is essential for visualization of the inflow and outflow vessels necessary for revascularization. CT angiography can be a noninvasive way to provide this information ([Fig. 97-6](#)).

Treatment

Indications

Surgical treatment is indicated for all symptomatic and many asymptomatic aneurysms. Controversy exists regarding the optimal management of small asymptomatic popliteal aneurysms because the natural history is not well defined. The incidence of complications with popliteal artery aneurysms is high, and the occurrence of complications does not correlate with the size of the aneurysm because the most common complications are embolization and thrombosis, which are not size related. In fact, in some reports the average diameter of symptomatic aneurysms is smaller than asymptomatic lesions.⁴⁰ These considerations, and the significantly higher limb loss rate after complications even when intervention is undertaken, has resulted in the recommendation for operative treatment when a popliteal aneurysm is diagnosed.

The goals of surgical treatment are to eliminate the potential for complications and to preserve or restore adequate blood flow to the limb. In patients with multiple aneurysms, the operative approach must be individualized. Generally, the life-threatening aortic aneurysm is treated first, followed by repair of the popliteal aneurysm. On the other hand, if a limb-threatening complication has occurred, treatment of the popliteal aneurysm usually takes precedence, followed by expeditious aortic aneurysm repair.

Figure 97-5. Arteriogram demonstrating a popliteal aneurysm associated with occlusion of the outflow tract presumably from repeated episodes of embolization. A bypass to the distal posterior tibial artery was successful.

Figure 97-6. Computed tomography arteriogram demonstrating right popliteal artery aneurysm and associated inflow and outflow.

Surgical Technique

Most popliteal aneurysms are easily approached through standard medial thigh and calf incisions for exposure of the distal superficial femoral artery and the distal popliteal artery, respectively. The proximal anastomosis will need to originate from the common femoral artery if the entire superficial femoral artery is aneurysmal. Occasionally, the posterior approach is preferred for lesions confined to the popliteal fossa, especially when accompanied by symptoms due to compression of adjacent structures. Most aneurysms are left in situ, bypassed using a segment of saphenous vein, and ligated proximally and distally. The conduit of choice for bypass is autologous saphenous vein, which is harvested from the thigh, reversed, and tunneled along the course of popliteal artery. The proximal and

distal anastomosis may be either end-to-end or end-to-side in configuration, with the aneurysm excluded from the circulation by proximal and distal ligatures. Ligation should be adjacent to the aneurysm to minimize the number of patent collaterals that are in continuity with the aneurysm.⁴¹ Late expansion and rupture of a bypassed and ligated popliteal aneurysm can occur when patent geniculate arteries continue to perfuse and pressurize the aneurysm. When the distal popliteal and proximal tibial vessels are occluded with recent emboli, they can sometimes be cleared using a balloon catheter or intraoperative thrombolytic therapy. Frequently, bypass grafts must be carried to the distal tibial arteries. Extensive femoral and popliteal aneurysms may require a femoral-popliteal or femoral-tibial bypass using in situ saphenous vein that originates from a prosthetic graft replacing a common femoral artery aneurysm.

Popliteal aneurysms have been treated by an endovascular approach. Small series show a primary patency rate of about 50% at 14 to 18 months,^{42,43} and a cumulative patency of 74%,⁴⁴ suggesting that this approach should be reserved for the more high-risk patient who requires intervention.

6 The patient who presents with an acutely ischemic extremity secondary to popliteal aneurysm thrombosis is a management challenge. Popliteal aneurysms often thrombose because of repeated episodes of emboli to the outflow vessels, which result in their occlusion. An expeditious arteriogram may identify a suitable outflow vessel for the bypass graft. If no target vessel is identified, intra-arterial thrombolytic therapy should be initiated with the goal of lysing thrombus in the tibial arteries to identify a suitable outflow vessel for vascular reconstruction. Although the embolic process may be chronic, results with thrombolytic therapy followed by bypass of the aneurysm have been much better than surgical therapy alone for the patient with an acutely occluded aneurysm and severe leg ischemia.

Results

Excellent results are obtained in asymptomatic aneurysms with intact distal vasculature. Patients with thrombosed aneurysms or those in whom multiple episodes of embolization have occluded the tibial arteries have less optimal results. Operative mortality is in the 0 to 2% range, with asymptomatic patients fairing better than those presenting with acutely symptomatic lesions.^{45,46} In patients undergoing revascularization before ischemic complications occur, 5- and 10-year graft patency rates are greater than 80% and limb salvage is 93% to 98%.^{35,47} Graft patency rates in patients undergoing surgery after developing complications of their aneurysms are 60% and 48% at 5 and 10 years, respectively, and limb salvage rates are 60% to 80%.^{35,47–49} Thrombolytic therapy, when successful, improves primary graft patency in patients presenting with acute limb ischemia.⁵⁰

Chapter 98

Venous Disease

Thomas W. Wakefield and Michael C. Dalsing

Key Points

- 1 The diagnosis and treatment of acute and chronic venous disease have made significant advances in the last decade.
- 2 New drug therapies exist or are on the verge of impacting the treatment of acute deep venous thrombosis (DVT).
- 3 Chronic venous disease has experienced a resurgence of interest in the United States with new endoluminal and surgical interventions being investigated and utilized clinically.
- 4 Characterization of the disease is being scrutinized to allow for a better understanding of how treatment truly impacts patient outcomes.
- 5 The care of venous disease is an active and maturing discipline within the realm of the surgical disciplines.

INCIDENCE, RISK FACTORS, AND CATEGORIES

Venous thromboembolism (VTE), including deep venous thrombosis (DVT) and pulmonary embolism (PE), is a national healthcare concern. DVT affects greater than 250,000 patients annually, whereas PE affects greater than 200,000 patients per year. The incidence has remained constant since 1980 and increases with age.¹ The cost of treatment for both DVT and PE (termed VTE) is in the billions of dollars per year. Although Virchow triad of stasis, vessel wall injury, and hypercoagulability have defined the events that predispose to DVT formation for the past 150 years, today the understanding of events that occur at the level of the vein wall including the influence of the inflammatory response on thrombogenesis is increasingly being recognized.

Acquired risk factors for VTE include increasing age, malignancy, immobilization, surgery and trauma, oral contraceptive use, hormone replacement therapy, pregnancy and the puerperium, neurologic disease, cardiac disease, obesity, and antiphospholipid antibodies.² Genetic risk factors include deficiencies of antithrombin, protein C and protein S, factor V Leiden, prothrombin 20210A, blood group non-O, dysfibrinogenemia, dysplasminogenemia, hyperhomocystinemia, reduced heparin cofactor II activity, elevated levels of clotting factors (e.g., factors XI, IX, VII, VIII, X, and II), and elevations in plasminogen activator inhibitor-1 (PAI-1).³ When a patient presents with an idiopathic VTE, there is family history of VTE, there is recurrent thrombosis, or there is thrombosis in unusual locations, workup for a hypercoagulable state may be indicated (hypercoagulable testing; [Table 98-1](#)).^{2,3} Hematologic diseases associated with VTE include heparin-induced thrombocytopenia and thrombosis syndrome, disseminated intravascular coagulation, antiphospholipid antibody syndrome, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and myeloproliferative disorders.

Most DVTs affect the iliac, femoral, or popliteal lower limb veins. Presenting symptoms include unilateral leg pain and swelling, but some DVTs are silent, with the first manifestation a PE. A recent study of 5,451 patients with ultrasound confirmed DVT revealed the most common comorbidities to be hypertension, surgery within 3 months, immobility within 30 days, cancer, and obesity.⁴

Venous Thromboembolism Diagnosis

1 Venous color duplex imaging is now standard, although D-dimer may be considered in low probability settings. The positive and negative predictive values for gray-scale imaging are inferior to color imaging. A meta-analysis of 13 studies comparing CT with ultrasound for proximal DVT found a sensitivity of 71% to 100% and specificity between 93% and 100%.⁵ In symptomatic patients, sensitivity is approximately 93%, specificity 98%, accuracy 97%, with approximately 30% of studies indeterminate

in the calf.⁶ Data from the Prospective Investigation of Pulmonary Embolism Diagnosis II, a multicenter study of 711 patients, were used to compare the clinical value of CT Venography (CTV) after multidetector CT angiography (CTA) with venous compression ultrasonography for the diagnosis of VTE. There was 95.5% concordance between CTV and ultrasonography for the diagnosis or exclusion of DVT ($\kappa = 0.809$). Attesting to the accuracy of ultrasound, the sensitivity and specificity of combined CTA and CTV were equivalent to combined CTA and ultrasonography.⁷

The usefulness and absolute need for duplex imaging depend, to some degree, on the pretest probability for DVT. In a patient with a low pretest probability for DVT (such as a Wells score), if a D-dimer biomarker test is negative, no further testing is necessary.⁸ D-Dimer requires that a high-sensitivity D-dimer assay (such as the advanced turbidimetric method or ELISA) is used. If the D-dimer is positive, then duplex must be performed even if the pretest probability is high, as a positive D-dimer and a positive risk assessment is associated with DVT in only approximately 70% of cases.⁹ A highly soluble P-selectin, along with a positive Wells score, may allow for the diagnosis of DVT in greater than 90% of cases.¹⁰ The high negative predictive value (NPV) of color duplex Doppler ultrasound both above and below the knee supports withholding anticoagulation on the basis of a good-quality negative study alone, and clinical data also support that strategy.¹¹ A single good-quality color duplex Doppler study is sufficient (NPV >99.5%) to exclude proximal DVT; repeat scanning is seldom indicated unless the initial study was technically suboptimal.¹² A truly negative study means that all the segments of the leg, including the external iliac, common femoral, femoral, popliteal, and calf veins, are negative by ultrasound imaging and clear by Doppler flow. In a patient with a moderate pretest probability for DVT, if duplex ultrasound is negative, no further testing is necessary. On the contrary, in a patient with a high pretest probability for DVT, the D-dimer is less useful and even a negative result would not supersede the need for imaging. The positive predictive value is high for symptomatic patients with a positive duplex ultrasound and such patients should undergo treatment. If duplex ultrasound of proximal veins is negative, either perform D-dimer (if negative, withhold anticoagulation and if positive, repeat in 1 week) or just repeat in 3 to 7 days (3 days if very suspicious, 7 days if less suspicious). If whole leg duplex is negative, no further testing is necessary. During pregnancy the aforementioned recommendations remain, but it is very important to attempt to assess for iliac vein thrombosis.

Table 98-1 Alternative Anticoagulants

Drugs	Mechanism of Action
Dabigatran etexilate	Direct thrombin (FIIa) inhibitor
Bivalirudin	Direct thrombin (FIIa) inhibitor
Argatroban	Direct thrombin (FIIa) inhibitor
Fondaparinux	Indirect FXa inhibitor
Rivaroxaban	Direct FXa inhibitor
Apixaban	Direct FXa inhibitor
Edoxaban	Direct FXa inhibitor
P-selectin inhibitors	Anti-inflammatory preventing thrombus amplification

For the diagnosis of superficial vein thrombophlebitis (SVT), duplex ultrasound is also important.¹³ In a prospective epidemiologic study, including 844 patients with symptomatic SVT, 210 (24.9%) had concomitant DVT at the time of diagnosis of SVT. Of the 600 patients without DVT, over the next 3 months, 58 (10.2%) developed thromboembolic complications, including 3 (0.5%) with PE, 15 (2.8%) with DVT, 18 (3.3%) with extension, and 10 (1.9%) with recurrence of SVT. These events occurred despite the use of anticoagulant treatment. Thus, it is important to perform good duplex imaging in patients diagnosed with SVT.

Finally, in the CALISTO study, fondaparinux (Arixtra) was found effective in limiting a series of endpoints including death, PE, DVT, and extension or recurrence at days 47 and 77 after SVT diagnosis.¹⁴ This was in patients with axial vein SVT of at least 5-cm length with the thrombus at least 3 cm from the saphenofemoral junction (SFJ). Less extensive SVT requires only symptom control with oral or topical nonsteroidal anti-inflammatory drugs (NSAIDs). Thus, it is important to document the length of the SVT, the location, and the extent of the SVT to the SFJ, when imaging.

Other conditions may be confused with DVT and include lymphedema, muscle strains, and muscle contusion. Iliac vein obstruction may lead to unilateral leg edema (May–Thurner syndrome), while the presence of a cyst behind the knee may produce unilateral lower leg pain and edema. Other causes of

leg swelling include systematic problems such as cardiac, renal, or hepatic abnormalities. These systemic problems usually lead to bilateral edema.

Pulmonary Embolism

Testing for PE begins with prior probability estimation for all patients. Two of the most widely known and validated diagnostic scoring systems are the Wells criteria (or modified/dichotomous Wells criteria) and Geneva score.¹⁵⁻¹⁷ They use a combination of physical examination, history, and vital signs to predict the likelihood of PE. D-Dimer testing is used to exclude PE for patients with low prior probability for DVT. D-Dimer testing has no role in diagnosis if prior probability is not low. Use of D-dimer testing in PE diagnosis requires that a high-sensitivity D-dimer assay (such as the advanced turbidimetric method or ELISA) validated at the local institution be used. Patients with both low probability and negative D-dimer require no further investigation as the NPV is 99%.^{18,19}

The diagnosis of PE has involved ventilation-perfusion (V/Q) scanning and pulmonary angiography. However, newer techniques include spiral computed tomographic scanning and magnetic resonance imaging. The sensitivity of V/Q scanning was defined in PIOPE I at 98%, but specificity was low at 10%.²⁰ By combining clinical factors with V/Q scan, levels of sensitivity and specificity greater than 95% were achieved. With a high-probability V/Q scan, two risk factors positive for PE, the sensitivity was 97%; with one risk factor, 84%; and with no risk factors, 82%. Similarly, with a normal V/Q scan, the chance of PE was essentially 0, irrespective of the risk factor status.²¹ Thus, a normal V/Q scan or a high-probability scan provided good diagnostic information that could be used to base treatment on. However, only a small portion of V/Q scans are in one of these two categories, leaving many patients needing further testing. Because of its invasive nature, pulmonary angiography is used less often today. Pulmonary arteriography is included with acute massive PE, inferior vena cava (IVC) interruption, and when planning interventional therapy, such as thrombolysis or pulmonary embolectomy.

Multidetector helical CTA is the primary imaging modality, although V/Q scanning remains viable (particularly for patients with otherwise normal lungs in whom interpretability of the test is optimal), and a positive lower-extremity color duplex Doppler study in a high-probability patient can establish the diagnosis of VTE without lung imaging. However, the problem with using only lower extremity duplex imaging is that a baseline study in the chest is not obtained for later comparisons. Multidetector scanners have significantly improved the sensitivity and specificity, as well as the positive and negative predictive value of CTA. Recent outcome studies have found the sensitivity and specificity of CTA to be greater than 95%, and a negative CTA carries a 3-month risk of VTE of 1% to 2%. CTA establishes the diagnosis of PE if it is positive in an intermediate- or high-probability patient, or in a low-probability patient with findings of a main-stem or lobar embolus. It excludes the diagnosis of PE in low-probability patients with negative scans. Discordance between prior probability and CTA findings requires further investigation, as well as technically inadequate studies.⁷ Other diagnostic tests may include V/Q imaging or pulmonary angiography.

Outcome studies have found comparable results between pulmonary angiography and CTA; a negative result with either study confers approximately a 1% VTE rate within 6 months. However, because angiography is invasive, it carries a greater risk of complications and mortality. The mortality from angiography has been estimated at 0.5%, while 1% may experience major complications, including arrhythmias, hypotension, bleeding, and nephrotoxicity.²² Without a higher standard to appeal to, one cannot discuss specificity and sensitivity of pulmonary angiography using commonly accepted definitions of these terms. Instead, the accuracy of pulmonary angiography is discussed in terms of interobserver variability in the reading of pulmonary angiograms obtained in the context of large multicenter trials. Studies demonstrate that the larger the embolus, the better the interobserver agreement. For segmental and larger emboli, agreement exceeds 95%. For subsegmental emboli, agreement is considerably less. We do not recommend pulmonary angiography, except in certain circumstances, such as with inadequacy of V/Q imaging or when catheter-directed thrombolysis is recommended.

Recently, the efficacy of magnetic resonance angiography (MRA), magnetic resonance venography (MRV), or the combination of the two in the diagnosis of acute PE has been studied.²³ The gold standard used for comparison was a composite end-point of CTA, CTA-CTV, V/Q scan, lower extremity ultrasonography, D-dimer assay, and clinical assessment. Overall, MRA and MRA-MRV were found to be poor tests for the diagnosis of PE. Approximately 25% of the 371 patients enrolled in a large multicenter study had a technically inadequate MRA, and 48% had either an inadequate MRV or MRA. Considering all patients enrolled, MRA alone identified only 57% of PEs and had a sensitivity of 78%

when only patients with adequate studies were considered. The combined MRA-MRV studies had a sensitivity of 92%, but only about half of the patients had technically adequate studies. These poor results are generally felt related to the technical difficulties of MRA in identifying abrupt vessel termination and capturing adequate images of the chest vessels secondary to motion artifact. At this time, MRA-MRV is not generally recommended and only considered in centers with a great deal of experience.

Because of its low sensitivity and specificity, transthoracic or transesophageal echocardiography has limited diagnostic value for PE.²⁴ For critically ill patients too unstable for transport, echocardiography can suggest the diagnosis of PE by showing dilatation of the RV or hypokinesis. Commonly, acute changes in the RV pressure, size, and function are seen, indicating increased RV strain and pulmonary arterial pressures. These changes suggest PE in the absence of alternative diagnoses. Although of limited value in the diagnosis of PE, echocardiography is of great prognostic use in stratifying risk for patients with acute PE. Right ventricular dysfunction or dilatation in acute PE is associated with worse outcomes, including increased mortality rate.

Biomarkers include B-type natriuretic peptide (BNP), released by ventricular myocardial cells in response to wall stretch and volume overload. BNP is a prognostic (not diagnostic) biomarker for PE. BNP levels generally indicate RV strain due to elevated pulmonary vascular resistance in the lungs. If measured early (within 4 hours of admission for PE), elevated BNP levels (>90 pg/mL) demonstrate a sensitivity of 85% and a specificity of 75% in predicting PE-related outcomes. Conversely, normal BNP values in the setting of acute PE carry a 97% to 100% NPV for in-hospital death. Another biomarker is troponin released from damaged myocardial cells. When elevated in acute PE, troponins represent myocyte ischemia and microinfarction due to acute cardiac strain of the right ventricle. Approximately 30% to 50% of patients with large PE will have elevations in troponins I and T that are mild and short-lived. They correlate with worse RV function and a high incidence of complications. Normal troponin T levels have a 97% to 100% NPV for in-hospital death. These two biomarkers are not part of routine algorithms.¹⁹

Axillary/Subclavian Vein Thrombosis

Thrombosis of the axillary/subclavian vein accounts for less than 5% of all cases of acute DVT. However, it may be associated with PE in up to 10% to 15% of cases and additionally can also be the source of significant disability.²⁵ Primary axillary/subclavian vein thrombosis results from obstruction of the axillary vein in the thoracic outlet, the so-called Paget-Schroetter syndrome, noted especially in healthy muscular athletic individuals. Such thrombosis may also occur in patients with hypercoagulable states. Secondary axillary/subclavian vein thrombosis results from mediastinal tumors, congestive heart failure, and nephrotic syndrome. Patients with axillary-subclavian venous thrombosis often present with arm pain, edema, and cyanosis. Superficial venous distension may be apparent over the arm, forearm, shoulder, and even the anterior chest wall.

Upper extremity venous duplex ultrasound is used to diagnose suspected axillary-subclavian vein thrombosis. Thrombolysis and phlebography are often considered next. If phlebography is performed, it is important that the patient undergo positional phlebography with arm abduction to 120 degrees to confirm extrinsic subclavian vein compression at the thoracic outlet. Venous compromise is further evidenced by prominent collateral veins. Since a cervical rib may be the cause of such obstruction, chest x-ray film should be obtained to exclude its presence.

STANDARD THERAPY FOR VTE

Treatment

The traditional treatment of VTE is systemic anticoagulation, which reduces the risk of PE, extension of thrombosis, and thrombus recurrence. Immediate anticoagulation should be undertaken as the recurrence rate for VTE is higher if anticoagulation is not therapeutic in the first 24 hours.²⁶ For DVT, since duplex imaging is rapidly obtained, usually testing precedes anticoagulation while for PE, anticoagulation is recommended either simultaneous with or before testing. Recurrent DVT can still occur in up to one third of patients over an 8-year period, even with appropriate anticoagulant therapy.²⁷

Unfractionated heparin or low-molecular-weight heparin (LMWH) is given along with oral anticoagulation with vitamin K antagonists (usually warfarin [Coumadin]). It is recommended that the

international normalized ratio (INR) be therapeutic for 2 consecutive days before stopping heparin or LMWH.²⁸ LMWH has become the standard for treatment because it is administered subcutaneously, requires no monitoring (except in certain circumstances, such as renal insufficiency or morbid obesity), and is associated with a decrease in bleeding potential.²⁹ Compared to standard unfractionated heparin, LMWH has significantly improved bioavailability, less endothelial cell binding and protein binding, and improved pharmacokinetics.³⁰ The half-life of LMWH is dose independent and it is administered in a weight-based fashion. LMWHs may decrease indices of chronic venous insufficiency (CVI) compared with standard therapy when used over an extended period. Based on all of the available evidence, LMWH is now preferred over standard unfractionated heparin for the initial treatment of VTE with a level of evidence given 2B (according to the 2012 Chest consensus guidelines).³¹ Warfarin should be started after heparinization is therapeutic to prevent warfarin-induced skin necrosis, as warfarin causes inhibition of protein C and S before factors II, IX, and X, leading to paradoxical hypercoagulability at the initiation of therapy. For standard unfractionated heparin, this requires a therapeutic activated partial thromboplastin time; for LMWH, warfarin is administered after an appropriate weight-based dose of LMWH is administered and allowed to circulate.

The goal for warfarin dosing is an INR between 2.0 and 3.0. The duration of anticoagulation depends on a number of factors, including the presence of continuing risk factors for thrombosis, the type of thrombosis (idiopathic or provoked), the number of times thrombosis has occurred, the status of the veins when stopping anticoagulation, and the level of D-dimer measured approximately 1 month after stopping warfarin. One study demonstrated a statistically significant advantage to resuming warfarin if the D-dimer assay is elevated over an average 1.4-year follow-up (odds ratio [OR], 4.26), and a meta-analysis has confirmed this relationship.³² The recommended duration of anticoagulation after a first episode of VTE is 3 months.³¹ After a second episode of VTE, the usual recommendation is prolonged warfarin unless the patient is very young at the time of presentation or there are other mitigating factors. VTE recurrence is increased with homozygous factor V Leiden and prothrombin 20210A mutation, protein C or protein S deficiency, antithrombin deficiency, antiphospholipid antibodies, and cancer until resolved. In these situations, long-term warfarin is recommended. However, heterozygous factor V Leiden and prothrombin 20210A do not carry the same risk as their homozygous counterparts, and the length of oral anticoagulation is shortened for these, the most common of hypercoagulable conditions. Regarding idiopathic DVT, most believe that this diagnosis requires longer than 6 months of anticoagulation, but the actual length is unknown.³³ Taken together, criteria for discontinuing anticoagulation are given a level of evidence of 1B to 2B, depending on the clinical situation.^{31,33–37} Recent evidence suggests that the decision to continue anticoagulation indefinitely after a first unprovoked proximal DVT is strengthened if the patient is male, the index event was a PE, and the D-dimer is positive 1 month after stopping anticoagulation.³⁸ In addition, there is growing evidence that in certain circumstances, such as active cancer, the use of LMWH is superior to LMWH converted to warfarin for long-term treatment.

Complications

Bleeding is the most common complication of anticoagulation. With standard heparin, bleeding occurs over the first 5 days in approximately 10% of patients.³⁹ Heparin-induced thrombocytopenia (HIT) occurs in 0.6% to 30% of patients. Although historically morbidity and mortality rates have been high, it has been found that early diagnosis and appropriate treatment have decreased these rates.⁴⁰ HIT usually begins 3 to 14 days after heparin is begun, although it can occur earlier if there has been exposure to heparin in the past. A heparin-dependent antibody binds to platelets, activates them with the release of procoagulant microparticles leading to an increase in thrombocytopenia, resulting in thrombosis.⁴¹ Both bovine and porcine unfractionated heparin and LMWH have been associated with HIT, although the incidence and severity of the thrombosis are less with LMWH. Even small exposures to heparin can cause the syndrome. The diagnosis should be suspected with a 50% or greater drop in platelet count, when the platelet count falls less than 100,000/mL or when thrombosis occurs during heparin or LMWH therapy.⁴² A highly sensitive but poorly specific ELISA test detects the antiheparin antibody in the plasma. The serotonin release assay is another test that is more specific but less sensitive.⁴³ When the diagnosis is made, heparin must be stopped and warfarin should not be given until an adequate alternative anticoagulant has been established and the platelet count has normalized. LMWHs cannot be used as substitutes as studies demonstrate high cross-reactivity with standard heparin antibodies. Agents that have been approved by the Food and Drug Administration (FDA) as alternatives include the direct thrombin inhibitor argatroban and bivalirudin (Table 98-1). Fondaparinux has also

been found effective for treatment of HIT, but it is not FDA approved for this indication. The use of these alternative agents is given 2C and 1C evidence.⁴⁴

Low–Molecular-Weight Heparin Special Features

When considering once-a-day to twice-a-day LMWH dosing, a meta-analysis of greater than 1,500 patients with VTE demonstrated a nonsignificant difference in the incidence of recurrent thromboembolism, thrombosis size, hemorrhagic events, and mortality.⁴⁵ Twice-a-day dosing may still be more appropriate than once-a-day dosing in patients with marked obesity and patients with cancer.⁴⁶

LMWH has been suggested as a replacement for oral vitamin K antagonists. Rates of recanalization have been reported to be higher in certain venous segments using LMWH and the use of LMWH has been found to lead to improved outcomes in cancer patients compared to standard heparin or LMWH/warfarin therapy when used for 6 months, without differences in rates of major bleeding.⁴⁷ LMWH has also been found to provide better DVT prophylaxis than placebo when used for extended prophylaxis over 4 weeks in patients undergoing abdominal and pelvic cancer surgery.⁴⁸

ALTERNATIVE/FUTURE MEDICAL TREATMENTS FOR DVT

Fondaparinux targets factor Xa with a 17-hour half-life for fondaparinux (Table 98-1). It exhibits no endothelial or protein binding and produces no thrombocytopenia. One disadvantage is the lack of a readily available antidote. Fondaparinux has been tested in the prophylaxis of major orthopedic surgery. In a meta-analysis involving greater than 7,000 patients, there was more than a 50% risk reduction using fondaparinux begun 6 hours after surgery compared with LMWH begun 12 to 24 hours after surgery.⁴⁹ Critical bleeding was not different, although major bleeding was increased. Fondaparinux has also been effective in prophylaxis of general medical patients, abdominal surgery patients, and for extended prophylaxis after hip fracture.^{50–52} For DVT treatment, fondaparinux was found equal to LMWH, while for PE, it was found equal to standard heparin.^{53,54} Dosage is based on body weight: 5 mg per body weight <50 kg; 7.5 mg per body weight 50 to 100 kg; and 10 mg per body weight >100 kg. Treatment at least for 5 days with concurrent administration of oral anticoagulation is recommended, until the INR is therapeutic at a level of 2 to 3. Fondaparinux has been approved for the treatment of DVT/PE, and for thrombosis prophylaxis in total hip, total knee, and hip-fractured patients, in the extended prophylaxis of hip-fractured patients, and in abdominal surgery patients. A number of novel oral anticoagulants are currently developed or in stages of development to either replace vitamin K antagonists in concert with initial heparin or LMWH, or to replace both heparin/LMWH and vitamin K antagonists totally as monotherapy. These agents hold the promise of not needing monitoring, being safer in terms of bleeding risk than current agents, and being of equal or improved efficacy to established anticoagulants.

2 Dabigatran targets activated factor II (factor IIa), while rivaroxaban, apixaban, and edoxaban target activated factor X (factor Xa). Dabigatran etexilate is FDA approved for stroke and systemic embolization prevention in patients with atrial fibrillation and for treating deep vein thrombosis (DVT) and PE in patients who have been treated with a parenteral anticoagulant for 5 to 10 days. In trials for VTE, out of six randomized controlled trials (RCTs), dabigatran was noninferior in three trials, superior in two trials, and inferior in one trial. In the Recover trial, which compared dabigatran 150 mg to therapeutic anticoagulation with vitamin K antagonists (INR, 2 to 3) in the treatment of DVT for 6 months, after both were given LMWH or unfractionated heparin for an average of 9 days, dabigatran was noninferior in the 6-month rate of VTE recurrence. In addition, clinically significant bleeding was not significantly different when compared with warfarin.⁵⁵ In addition, in two other VTE trials, dabigatran was found in extended duration treatment to have fewer recurrent VTEs compared with placebo.⁵⁶ Rivaroxaban is FDA approved for VTE prophylaxis in patients undergoing hip or knee replacements, for stroke and systemic embolization prevention in patients with atrial fibrillation, and for VTE treatment. Eight major trials studying VTE and rivaroxaban have been published, with rivaroxaban noninferior in 6 and superior in 2 to standard therapy. The Einstein trial evaluated rivaroxaban compared to standard anticoagulation in the treatment of acute DVT.⁵⁷ As monotherapy, rivaroxaban was found statistically noninferior to standard therapy, without increased bleeding risk. In addition, the Einstein group added a continued treatment group compared to placebo for an additional 6 to 12 months. Extended rivaroxaban showed a significant decrease in recurrent VTE without an increase in major bleeding. A similar finding with PE has been noted.⁵⁸ In a trial for atrial fibrillation,

rivaroxaban showed statically less intracranial bleeding or fatal bleeding.

Apixaban is currently FDA approved for the prevention of complications of atrial fibrillation, for prophylaxis of DVT following hip or knee replacement surgery, for the treatment of DVT/PE, and for reduction in the risk of recurrence of DVT/PE. This agent has been evaluated in six studies involving VTE, noninferior in two, superior in three, and a failure in one. In a recent study, Apixaban was given for 7 days of initial treatment for DVT, followed by a lower dose bid versus standard enoxaparin followed by warfarin for 6 months. Apixaban was noninferior to standard therapy with less bleeding.⁵⁹ Apixaban was also studied as extended treatment of VTE.⁶⁰ After a standard duration of treatment, an additional 12 months of apixaban therapy compared to placebo revealed a significant decrease in the rate of VTE without an increase in bleeding. This is the only new oral agent that has revealed superiority to standard therapy without an increase in bleeding in atrial fibrillation patients. Edoxaban administered once daily after initial treatment with heparin was noninferior to high-quality standard therapy and caused significantly less bleeding in a broad spectrum of patients with VTE, including those with severe PE.⁶¹ Problems with these new agents include the difficulty at the present time to reliably reverse the anticoagulant effects of these drugs with only one approved medication available at the present time, the fact that there is little data available on bridging of these agents when other procedures need to be performed, and the fact that they are nongeneric. Their usefulness for VTE will dramatically improve when adequate reversal agents become clinically available.⁶² The use of P-selectin inhibitors, an area of ongoing research, uses an anti-inflammatory approach to limit thrombus amplification without causing anticoagulation.

NONPHARMACOLOGIC TREATMENTS

Postthrombotic syndrome (PTS) results from loss of competence of the venous valves as a result of DVT or persistent venous obstruction, or a combination of both. It can cause significant morbidity in the form of pain, swelling, skin breakdown, and ulcerations. A Cochrane meta-analysis found a strong effect (OR 0.31) for prevention of PTS using graduated compression stockings beginning within 2 weeks of onset of DVT, with important data highlighted from two open-labeled randomized single-center studies that utilized stockings of 30 to 40 mm Hg for 2 years after DVT.⁶³ From these data, stockings of 30 to 40 mm Hg gradient should be recommended to most patients with DVT, for a minimum of 2 years post-DVT, and longer if they have symptoms of PTS. There is a new study that would suggest that stockings may not prevent PTS after a first proximal DVT.⁶⁴ However, there are a number of specific considerations in this study that will need to be repeated before the recommendation of stockings after DVT is reversed. In addition, ambulation with good compression does not increase the risk of PE, while significantly decreasing the incidence and severity of the PTS.^{65,66} Early ambulation has the potential to decrease PTS and improve patients' quality of life (QOL). Thus, patients should be encouraged to ambulate as part of their post-DVT care recommendations.³¹

IVC Filters

The traditional indications for the use of IVC filters include a complication of anticoagulation, a contraindication to anticoagulation, and failure of anticoagulation. Protection from PE has been greater than 95% using cone-shaped wire-based permanent IVC filters.⁶⁷ Cone-shaped filters have a lower incidence of IVC thrombosis compared with basket-shaped filters, and a recent study between the two filter types was stopped early because of the high rate of IVC thrombosis with the basket-shaped device.⁶⁸ The success achieved with filters has expanded the indications, including free-floating thrombus longer than 5 cm, when bleeding risk with anticoagulation is excessive, when the risk of PE is felt to be very high, and to allow for the use of perioperative epidural anesthesia.^{69–71} Filters can be permanent or optional (retrievable). If a retrievable filter is left in to become a permanent filter, the long-term fate of that filter has yet been defined.

Filters are usually placed in an infrarenal location. However, they may also be placed in the suprarenal location or in the superior vena cava. Indications for suprarenal placement include high-lying clot, pregnancy, women of childbearing potential, or a previous device that has failed or become filled with clot. Sepsis is not a contraindication to the use of wire-based filters since the trapped material can be sterilized with antibiotics. Although filters have been placed under x-ray guidance, percutaneous techniques for filter insertion using bedside external ultrasound or intravascular ultrasound are now being recommended. Transabdominal external ultrasound is difficult in the face of morbid obesity,

overlying bowel gas, or open abdominal wounds. In these instances, intravascular ultrasound has been found to be more successful.⁷² Other than one randomized prospective study on the use of filters as treatment of DVT (which is not how filters are traditionally used), evidence for the use of filters is given a 2C level of evidence.^{73,74}

Thrombolytic and Surgical Procedures for Deep VTE

For DVT treatment, the goals are to prevent extension or recurrence of DVT, prevent PE, and minimize the late sequel of thrombosis, namely CVI. Standard anticoagulants accomplish the first two goals but not the third goal. The PTS (venous insufficiency related to venous thrombosis) occurs in up to 30% of patients after DVT and even greater with more proximal iliofemoral DVT.²⁷ Experimentally, prolonged contact of the thrombus with the vein wall increases damage.⁷⁵ The thrombus initiates an inflammatory response in the vein wall that can lead to vein wall fibrosis and valvular dysfunction. Systemic thrombolysis in two small series revealed a decrease in the incidence of CVI with streptokinase, as opposed to systemic unfractionated heparin (UFH). However, results depend on complete thrombolysis. Because of this inability to predict complete lysis, combined with its bleeding potential thrombolysis is recommended infrequently. However, urokinase administered directly into venous thrombi has led to an increase in enthusiasm and the publication of a national thrombolysis registry.^{76,77} In 473 patients, 287 of whom underwent follow-up, 312 urokinase infusions in 303 limbs were reported. Venous thrombi occurred in the iliofemoral segment in 71% of cases alone, without IVC involvement in 79%, and including the IVC in 21% of cases. Patients had acute disease in approximately two-thirds of cases, 16% had chronic disease, and 19% had combined acute and chronic disease. Approximately 30% had prior DVT. Complete thrombolysis was achieved in 31% and partial lysis in 52% of cases. The mean amount of urokinase used was 7.8 million units, and the mean time of infusion was 53.4 hours. Successful lysis was predicted by acute DVT and no history of prior DVT. Complications included major bleeding necessitating blood products in 11% and minor bleeding in 16%. Mortality rate was 0.4%, intracranial hemorrhage rate was 0.2%, and subdural hemorrhage rate was 0.2%. Total lysis was noted in only 31% of the entire series; however, in patients with acute iliofemoral DVT, no previous symptoms, and the use of the popliteal vein access site, total lysis was more frequent. At 12 months, patency was 79% if lysis was complete, 58% with greater than 50% lysis, and 32% with less than 50% lysis. Absence of valvular reflux was found in 72% of cases with complete lysis, whereas overall valvular reflux was seen in 58% of cases.

Importantly, aggressive therapies have been found to improve QOL. A small randomized study demonstrated that thrombolysis is superior to anticoagulation in patients with iliofemoral DVT.⁷⁸ Results appear to be optimized further by combining catheter-directed thrombolysis with mechanical devices, including the AngioJet™ rheolytic catheter, and the EKOS MicroSonic™ accelerated thrombolysis catheter. In addition, new devices (such as the Angiovac) are being developed specifically for large veins. With these devices, thrombolysis is hastened, the amount of thrombolytic agent is decreased, and bleeding is thus decreased. Importantly, a number of small studies have reported a decrease in PTS with catheter-directed thrombolysis for iliofemoral DVT⁷⁹ and long-term results have demonstrated patency rates over 80% with competent valves.⁸⁰ Postthrombotic morbidity correlates with residual thrombus.⁸¹ In addition, the use of venous stents for iliac venous obstruction has been shown to decrease the incidence of PTS and CVI.⁸² To more fully elucidate the role of aggressive therapy in proximal iliofemoral venous thrombosis, a study is in progress, supported by the National Institutes of Health, to compare catheter-directed pharmacomechanical thrombolysis to standard anticoagulation for significant iliofemoral venous thrombosis, with both arms also undergoing ambulation and stocking use. This study, the Attract Trial, will evaluate anatomic, physiologic, and QOL endpoints in addition to vascular laboratory endpoints and a careful evaluation of complications.

Thrombolytic therapy for PE remains controversial. Although agents lyse thrombus effectively, recurrence rates and patient mortality rate were not reduced. However, the original studies were not powered to address this outcome. Results are best if patients are young, the embolus is less than 48 hours old, and the embolus is large. Streptokinase, urokinase, and tissue plasminogen activator have all been used.⁸³ All agents rapidly dissolve clot, but by 7 days, the advantages for all three agents decrease. The benefit of thrombolytic agents for PE thus appears to be greatest in patients who would die as a result of massive PE in the first hour after the PE occurs, which can occur in up to 10% of cases. However, more recent data suggest that thrombolysis may be useful in patients with right ventricular dysfunction without hemodynamic instability and it has been suggested that thrombolysis will improve outcomes if patients have evidence of right-sided heart changes.^{84–89} In addition, thrombolysis therapy

has been recommended in patients without hypertension who are judged to have a low risk of bleeding.⁷³

Contributions to thrombolytic therapy include:

Absolute

- neurosurgery within 3 months
- active internal bleeding
- recent (<2 months) cerebrovascular accident
- intracranial disease
- recent gastrointestinal bleeding

Relative Major

- recent (<10 days) major surgery, obstetric delivery, or organ biopsy
- left-sided heart thrombus
- active peptic ulcer or gastrointestinal abnormality
- recent major trauma
- uncontrolled hypertension (systolic >180 mm Hg; diastolic >110 mm Hg)
- recent eye surgery

Relative Minor

- minor surgery or trauma
- recent cardiopulmonary resuscitation
- atrial fibrillation with mitral valve disease
- bacterial endocarditis
- hemostatic defects (i.e., renal or liver disease)

Venous Thrombectomy

Iliofemoral venous thrombectomy has been advocated to prevent impending venous gangrene. This technique results in mechanical clearing of the venous circulation and may be combined with a temporary arteriovenous fistula. Thrombectomy uses a Fogarty balloon catheter passed from the femoral vein during Valsalva maneuvers. An arteriovenous fistula is constructed so that it can be taken down by nonsurgical techniques. Complete venography in the operating room is recommended, as back-bleeding is unreliable for the assessment of complete thrombus clearance. Thrombosis recurrence rates less than 20% have been reported. The incidence of PE during the first week after thrombectomy is equivalent to the incidence with anticoagulation only. The frequency of clinical success has been reported to be between 42% and 93%.⁹⁰ The largest series of 77 legs with a follow-up period of between 5 and 13 years revealed maintenance of patency, but a steady decline in valvular competence over time.⁹¹

In the only comparative study of iliofemoral venous thrombosis treatment comparing thrombectomy with anticoagulation (31 patients) versus anticoagulation alone (32 patients), iliofemoral vein patency was improved (76% vs. 35%), femoropopliteal patency was improved (52% vs. 26%), and the clinical outcome was better at 6 months (40% asymptomatic vs. 7%).⁹¹ At 10 years, the number of patients available for follow-up had decreased to 13 in the thrombectomy group and 17 in the anticoagulation-alone group. Patency remained improved in the thrombectomy group (83% vs. 41%), and absence of popliteal reflux was found in 78% of the thrombectomy-plus-anticoagulation group compared with 43% of the anticoagulation group alone.

Pulmonary Embolectomy

Surgical approaches for PE are indicated for patients with massive PE with hypotension who require large doses of vasopressors. These are often patients in whom thrombolytic agents have been unsuccessful. Open pulmonary embolectomy is associated with high rates of morbidity and mortality. Today, open pulmonary embolectomy is limited to those who require manual cardiac massage for hypotension or those in whom catheter pulmonary embolectomy fails. However, there may be a more expanded role for pulmonary embolectomy in the future.⁹²

Superficial Thrombophlebitis

SVT is a well-recognized clinical entity, characterized by a painful erythematous and palpable cord-like structure, usually compromising the lower extremities but capable of affecting any superficial vein in

the body. Thrombophlebitis is believed to have a multifactorial etiology, in which Virchow triad of altered blood flow, changes in the vessel wall, and abnormal coagulation are recognized to play a significant role. SVT has been considered a benign disease requiring only conservative management with compression, nonsteroidal anti-inflammatory medications, and lower extremity elevation. Recently SVT, especially above the knee superficial thrombophlebitis, has been reported to coexist with DVT, to propagate to popliteal or femoral level and to even cause PE.⁹³⁻⁹⁷ A medical approach using anticoagulant therapy appears as the treatment of choice when there is above-knee SVT with deep venous system involvement.

The incidence of SVT occurs in approximately 125,000 people in the United States per year.⁹⁸ However, the actual incidence is likely far greater as these statistics may be outdated and many cases go unreported. Approximately 54% to 65% of the reported cases affect females with an average age of 58 years.^{93,99} The most frequent predisposing risk factor for SVT is varicose veins, occurring in 62% of patients. Other risk factors include immobilization, trauma, postoperative states, age >60 years, obesity, tobacco use, history of DVT or SVT, pregnancy, puerperium, autoimmune disease, use of oral contraceptives or hormonal replacement therapy, and hypercoagulable state.^{93,99,100} Hypercoagulable screening should be considered in patients with ascending or worsening thrombophlebitis despite initial treatment.^{101,102} Malignancy has been reported as a risk factor for developing SVT, affecting 13% to 18% of patients.^{96,103}

The overall recurrence of SVT was described as 18% over 15 months, equally frequent in varicose and nonvaricose phlebitis. Deep venous reflux increases the recurrence rate to 33%, while hypercoagulable states increase the recurrence rate to 42% over the same period of time.¹⁰⁴

The clinical symptoms and signs for SVT are overt. Duplex ultrasound imaging of the affected extremity should be performed to rule out extension of the process into the deep venous system or concomitant DVT.^{101,105} Duplex ultrasound shows the extent of the SVT, its relation to the veins connecting with the deep vein system, and the presence of concomitant DVT. In addition, duplex ultrasound allows checking the competence of the valves in the superficial and deep veins.¹⁰⁵

Complete thrombophilia workup is not routinely recommended. However, it may be indicated in selected patients with recurrent primary thrombophlebitis or aggressive thrombophlebitis.¹⁰⁵ Screening for underlying diseases, including malignancy or vasculitis, is performed if signs or symptoms suggest the presence of such a problem.¹⁰⁵

Treatment

Several therapeutic approaches have been proposed for patients with SVT. These include ligation or vein stripping of the affected vein, elastic stockings, NSAIDs to reduce pain and inflammation, and variable doses of unfractionated heparin or LMWH followed by oral anticoagulant therapy. There is no consensus on the optimal treatment of SVT in clinical practice.

The course of treatment for SVT should be tailored accordingly to its location and concomitant DVT if there is any associated infectious process. Thrombus location in trunks of either the great or small saphenous vein (SSV) may have the highest risk of extension into the deep vein system and thus require more aggressive treatment than other locations. The treatment for primary SVT localized in the distal great saphenous vein (GSV) and tributaries veins consists of ambulation, warm soaks, compression, and NSAID agents.^{106,107} If the patient presents risk factors for DVT, pharmacologic prophylaxis should be considered seriously.¹⁰⁵

Titon et al. were among the first to compare different approaches on the medical treatment of SVT.¹⁰⁸ In a multicenter study, 117 patients were randomized into 3 groups: fixed dose LMWH calcium nadroparin ($n = 38$), adjusted-dose LMWH calcium nadroparin ($n = 39$), and the NSAID naproxen ($n = 40$) for 6 days. At day 7, heat and redness were significantly less ($P < .001$) in both groups treated with LMWH compared with those given the NSAID. In addition, at 8 weeks, persistence of symptoms and signs was less frequent in the LMWH-treated groups ($P = 0.007$). Efficacy did not differ between the fixed and weight-adjusted doses of LMWH.

The management of SVT was further addressed in a randomized, double-blind study describing 427 patients with documented acute symptomatic SVT of the legs.¹⁰⁹ Patients were randomly assigned to receive 40 mg of enoxaparin sodium subcutaneously; 1.5 mg/kg of enoxaparin sodium subcutaneously; oral tenoxicam 20 mg; or placebo, all once daily for 8 to 12 days. LMWH was associated with a lower incidence of SVT extension and/or recurrence, compared with placebo (OR, 0.32; 95% confidence interval [CI], 0.16 to 0.65, and OR 0.33; 95% CI, 0.16 to 0.68, respectively), without major bleeding or HIT. There was no statistical difference with respect to 12-day outcomes between the active treatment

groups. However, there was a trend in favor of the LMWH.

The Vesalio Investigator Group compared two regimens of LMWH with each other.¹¹⁰ A total of 164 patients were enrolled and randomized into 2 groups: prophylaxis group ($n = 81$) and treatment group ($n = 83$). After completion of 3 months, the cumulative rate of SVT progression and VTE complications did not differ between the prophylactic (8.6%; 95% CI, 3.5 to 17.0) and therapeutic (7.2%; 95% CI, 2.8 to 15.1) groups. No patient in either group developed major bleeding, while one patient in each group developed a clinically asymptomatic HIT. Clinical symptoms improved to a similar extent in both groups, and similar rates of minor extension or recurrent thrombophlebitis were observed during the follow-up period.

Prophylactic dose intravenous (IV) UFH was used as a comparator treatment in two studies.¹¹¹ Relative to elastic stocking alone, prophylactic IV UFH plus elastic stockings was associated with an 86% reduction in SVT extension and/or recurrence (OR 0.14; 95% CI, 0.03 to 0.67). Marchiori et al.¹¹² compared high-dose versus low-dose IV UFH. A nonsignificant 86% reduction in VTE (OR 0.14; 95% CI 0.02 to 1.23) and a 37% (OR 0.63; 95% CI, 0.21 to 1.88) lower rate of SVT extension and/or recurrence were observed in those patients treated with high-dose UFH. There were no episodes of major bleeding and HIT.

LMWH was compared with saphenofemoral disconnection for the treatment of proximal GSV thrombophlebitis in a prospective, randomized clinical study.¹¹³ In this study, 84 consecutive patients diagnosed as presenting SVT alone were divided into 2 groups treated with saphenofemoral disconnection under local anesthesia with a short hospital stay ($n = 45$) or enoxaparin on an outpatient basis for 4 weeks ($n = 39$). In all, 30 patients per group completed the study requirements. In the surgical group, 2 patients (6.7%) presented complications of the surgical wound, 1 (3.3%) had SVT recurrence, and 2 (6.7%) had nonfatal PE. In the enoxaparin group, there was no progression of the thrombosis to the deep venous system or PE, there were 2 cases (6.7%) of minor bleeding and 3 (10%) recurrences of SVT. Even when the study found no statistically significant difference between the 2 groups in the treatment of SVT, the LMWH group demonstrated a significant socioeconomic advantage and confirmed the efficacy of LMWH treatment in resolving symptoms and signs and preventing DVT and PE.

Prophylactic-dose LMWH has the advantage over other equally efficacious techniques in resolving symptoms and signs and preventing DVT and PE in cases without concomitant DVT. Patients treated with LMWH do not require hospitalization, present less adverse effects, do not require laboratory monitoring in most situations, and have a low risk of bleeding, and treatment is less expensive if hospitalization is not required. It is generally felt that medical management with anticoagulants versus surgical treatment is somewhat superior for minimizing complications and preventing subsequent DVT and PE development. On the contrary, surgical treatment with ligation at the SFJ combined with stripping (with or without perforator interruption) appears to minimize superficial venous thrombus extension, which ultimately provides improved pain relief.¹¹⁴

Septic thrombophlebitis requires treatment with broad-spectrum IV antibiotics. If rapid resolution of the cellulitis occurs, no treatment beyond a short course of antibiotics and standard treatment for the superficial thrombophlebitis are required. However, if the patient becomes septic, excision of the infected vein is required. With positive blood cultures, an extended course of antibiotics specific for the identified organism is indicated additionally.

The majority of episodes of uncomplicated superficial thrombophlebitis respond to conservative management. However, the recurrence rate for superficial thrombophlebitis has been estimated between 15% and 20%.^{115–117} Finally, in the CALISTO study, fondaparinux was found effective in limiting a series of endpoints including death, PE, DVT, and extension or recurrence at days 47 and 77 after SVT diagnosis. This was in patients with axial vein SVT of at least 5-cm length with the thrombus at least 3 cm from the SFJ. Less extensive SVT requires only symptom control with oral or topical NSAIDs.¹⁴

Figure 98-1. Duplex image demonstrating the superficial compartment, which contains the saphenous compartment with great saphenous vein (GSV) (*straight arrow*) lying within and the deep compartment with femoral vessels (*curved arrow*) lying within.

CHRONIC VENOUS DISEASE

Normal Venous Anatomy

The lower extremity venous system is composed of deep, perforating, and superficial veins (Fig. 98-1).¹¹⁸ The common femoral, femoral, deep (profunda) femoral veins in addition to the popliteal and tibial/peroneal veins make up the deep system. The once named “superficial” femoral vein has been changed to simply “femoral vein” to prevent the confusion the term “superficial” implied when treatment of an actual DVT is required. The deep veins lie beneath the investing fascia of the muscles of the leg and thigh (the deep compartment). The saphenous veins have similarly undergone a change in name to the GSV and SSV to standardize the abbreviations that were otherwise extremely confusing. It has also become clear that the GSV and SSV lie within the subcutaneous tissue and surrounded by a separate saphenous compartment. The saphenous nerve lies within the GSV compartment below the knee, which places the nerve at risk of injury during surgery or percutaneous intervention, but if the associated sensory loss occurs, it appears to have little impact on the patient’s QOL in the long term.¹¹⁹ The sural nerve lies in close proximity to the SSV and within its compartment. The superficial veins that lie outside the saphenous compartment, but parallel to the GSV or SSV, are called accessory saphenous veins. The term *communicating vein* is now reserved for those veins that interconnect with other veins of the same system, and the term *perforating vein* is reserved for those that penetrate the muscular fascia to connect superficial to deep.¹¹⁸ In the past, perforating veins with rather constant anatomic location have been named after their discoverer (e.g., Crockett’s, Boyd’s perforators), but more descriptive terms designating location are now preferred.¹¹⁸ An excellent international consensus committee description of the standardized venous anatomy nomenclature of the leg and pelvic can be found in an article by Caggiati and colleagues.¹²⁰

The variability of the lower extremity venous system is well known, but only certain anatomic variations are of importance for current surgical practice. The popliteal and femoral veins have variable anatomy and are often duplicated much like the tibial veins. The deep femoral vein often connects directly or through tributaries to the popliteal vein. Although duplication of the GSV has been estimated to be present in up to 50% of patients in some studies, it is becoming evident that duplication of the true GSV lying within the saphenous compartment is much less common.^{121,122} The SFJ often has at least four branches in addition to the GSV, but the arrangement and precise location of the branches are quite variable. The most cephalic branch is generally the superficial epigastric vein and is of some importance in new techniques for managing GSV reflux since the vein acts as a landmark for percutaneous interventions and there is a desire to have it remain patent following the procedure. The SSV is rarely duplicated (4%).¹²³ Although the SSV appears to pierce the deep fascia in the upper third of the calf, in reality the membranous layer forming the roof of the SSV compartment is thickened while the muscular fascia disappears, which positions the SSV between the gastrocnemius muscle bellies.¹²³ In only 62% of limbs does the SSV actually end in the popliteal fossa and can well end above the crease of

the knee.¹²³ The anatomy of the perforating veins becomes extremely important when considering surgery aimed at preventing reflux into the lower leg. Certainly, removing the GSV will not prevent the impact of perforator reflux if one ignores the fact that the posterior tibial perforators (Cockett perforators of old) connect the posterior accessory GSV with the posterior tibial veins rather than the GSV proper. Similarly, not recognizing that paratibial perforators exist can result in an unsuccessful intervention aimed at preventing calf perforator reflux.¹²⁴

With the exception of foot veins, the valves promote blood flow from superficial to deep and from caudal to cephalad in direction. The valves are made of a fine connective tissue skeleton covered by endothelium and are generally bicuspid, delicate, and extremely strong. The tibial and peroneal veins contain about 7 to 19 valves each. The popliteal vein contains one or two valves and the femoral vein has generally three. About 70% of common femoral veins have a valve located within 1 cm of the inguinal ligament. Twenty-five percent of external iliac and 10% of the internal iliac veins have a valve.¹²⁵ The common iliac vein generally has no valves. The GSV usually has more than six valves (range, 4 to 25) with at least one valve within a few centimeters of the SFJ and the SSV has an average of 7 to 10 valves range, 4 to 13.¹²⁶ Perforating veins and even larger venules have venous valves.¹²⁵

Variable numbers of venous lakes (1 to 18 sinuses) are found in the soleus muscle. These sinuses are valveless, floppy channels linked to small-valved venous channels that prevent reflux to the superficial system. The sinuses empty into the posterior tibial vein in the proximal calf. Within the gastrocnemius muscle, there are interlacing valved venous networks that coalesce to form a pair of venous channels that empty into the popliteal vein. These intramuscular venous chambers store venous blood and are crucial to calf muscle pump function.

The veins of the abdomen and pelvis begin at the inguinal ligament as the external iliac vein that is joined medially by the internal iliac to form the common iliac vein. The internal iliac vein drains the pelvis via connections such as the obturator, gluteal, and internal pudendal veins and their interconnections. To the right of the fifth lumbar vertebrae and aorta, the common iliac veins join to form the IVC. Compression of the left iliac vein by the right common iliac artery can lead to a venous obstructive condition called May-Thurner syndrome. The IVC typically ascends to the right of the aorta and vertebral column terminating in the right atrium. Its direct tributaries are the lumbar veins, the right gonadal vein, the renal veins, the right suprarenal vein, the right inferior phrenic vein, and the hepatic veins. Other named veins generally join one of these tributaries to empty into the IVC. Because of the embryonic evolutions that lead to the “normal” IVC and its branches, variations are common. Duplication of the IVC occurs in 0.2% to 0.3% of cases, transposition or a left-sided IVC can occur in 0.2% to 0.5% of cases, and a retroaortic left renal (1.2% to 2.4%), and circumaortic left renal vein (1.5% to 8.7%) have also been reported.¹²⁷ In the face of IVC occlusion, veins of the chest and abdominal wall, the azygos and hemiazygos systems, and vertebral plexuses may play a prominent role in venous drainage of the lower extremities and abdominal/retroperitoneal cavity.

Normal Venous Physiology

Under conditions of low volume or external pressure, many veins lying within muscle are demonstrated by duplex scanning to collapse in an elliptical configuration consistent with a thin vein wall and the lack of in situ external support.¹²⁸ With muscular relaxation, veins within these compartments change from an elliptical to a circular configuration to accept venous blood being emptied from the superficial system and delivered to the lower extremity by arterial inflow. Compliance is very high; in fact, increasing the venous volume (VV) by over two and one half times results in only a 0- to 15-mm Hg increment rise in pressure.¹²⁹ This allows a significant amount of blood (at least 500 mL in the standing position) to become sequestered in the lower limb without a significant buildup of intraluminal pressure. However, once a vein reaches its full circular shape, further increases in VV result in a proportional increase in intraluminal pressure. The capacitance of the venous system has been met and sustained venous hypertension results in decompensation noted as edema. Normally, modest exercise of the muscles will expel the contained blood volume present in the veins and reset the capacitance of the venous system.

In contrast to intramuscular veins, duplex scanning demonstrates that large axial veins (e.g., femoral, popliteal) collapse in a circular manner. Supported/tethered on all sides by connective tissue, these veins are subject to equal external pressures along the vein wall and expand or collapse in a direct response to changes in volume.¹³⁰ Their compliance mimics that of an artery in that pressure changes are more reflective of volume changes. They are conduit rather than compliance vessels.

The calf muscle and possibly the thigh muscles act as a pump, the “peripheral heart,” which can

generate pressures of up to 300 mm Hg during exercise.¹²⁵ Muscle contraction propels the blood toward the heart and lungs via the cephalad conduit veins. The valves in the proximal superficial and deep veins open to allow blood to move forward in response to an increased distal pressure gradient. The perforating vein valves close to prevent venous blood reflux from deep to superficial veins, thereby preventing high pressures generated in the deep system from affecting superficial structures (i.e., skin, soft tissues). In addition, blood moves centrally during exercise by compression of the superficial veins between the deep fascia and skin, but the pressure generated is only 100 to 150 mm Hg.¹²⁵ As the calf muscle relaxes, the flow/pressure gradient falls and proximal vein valve closure prevents reflux (retrograde flow). Arterial blood then slowly fills the venous system; valves in the foot veins and perforating veins open to allow the deep veins to fill from the superficial system replenishing the calf muscle pump venous sinuses.

The vein valve functions in a four-phase cycle: opening, equilibrium, closing, and closed phase. During equilibrium, flow separation occurs at the valve edge, the flow splits into two streams with one of the streams directed into the valve sinus possibly aiding in a self-cleaning step (preventing stasis). When maximally open, the two cusps create about a 35% narrowing of the outflow lumen, which may aid in outflow.¹³¹ Interestingly, the majority of the cycle has the valve in the open position. Valve closure normally occurs within 0.5 to 1.0 second in response to retrograde blood flow and the loss of a pressure/flow gradient.^{132,133} Closure time is somewhat dependent on the stimulus to closure and a flow velocity of at least 30 cm/second is required.¹³⁴

An IV catheter placed into a foot vein can measure changes in venous pressure over time and with movement. These measurements reflect normal venous hemodynamics in the distal superficial venous system.¹²⁵ When lying flat, a person's normal lower extremity IV pressure is about 15 mm Hg, but with standing the pressure rises to reflect the hydrostatic pressure of a column of blood from the heart to the foot catheter most reflective of the patient's height (generally ± 90 mm Hg). A hemodynamic study of venous function involves pressure measurements obtained during controlled exercise. The venous filling time is the time required to arrive at a steady-state pressure after standing. Ten steps (1/second) causes a drop in pressure, and the lowest pressure, called the ambulatory venous pressure (AVP), is generally less than 45 mm Hg. The venous refilling time is the time required, following exercise and standing at rest, to reach the baseline erect pressure. It is normally greater than 20 seconds. This rather simplistic measurement reflects a complex interaction of the venous conduits, the property of the veins, and the action of the peripheral pump.¹³⁵ If one measures the venous pressure in deeper veins and in more central locations, the measurements would be considerably different, but such measurements are not commonly obtained in clinical practice.

Prevalence and Impact

3 Chronic venous disease (CVD) is a common, costly malady in Western countries. If one considers the entire spectrum of the disease, it affects more than 30 million Americans (more than half women).^{136,137} Varicose veins are observed in 15% to 25% of the adult population.^{138,139} *Chronic venous insufficiency* is defined as venous pathology that results in advanced clinical symptoms (edema to venous ulceration). Skin changes suggestive of venous disease are noted in 6 to 7 million US citizens, and venous ulcers occur in up to 2% of those with CVI (approximately 500,000 patients).^{136,140} Population studies confirm these earlier clinical observations.¹⁴¹ A population-based study that included Duplex imaging and utilized a modified CEAP classification (see later) demonstrated that in San Diego, 5.8% of those studied presented with edema while 6.2% had skin changes and/or prior or active venous ulcers.¹³⁹ The annual cost to treat venous ulcers alone is estimated at \$1 billion.^{142,143} It is interesting that similar findings are noted throughout Europe.^{144–150} Relevant risk factors for varicose veins are advanced age, a positive family history, female gender, multiparity, and obesity when based on epidemiologic studies,^{136,139,144,145,147,148,151} while the risk factors for CVI are advanced age, positive family history, and obesity.^{139,144,148,149}

Pathophysiology and Etiology

Three pathophysiologic states exist: obstruction, valvular insufficiency, and calf muscle pump malfunction. These conditions reflect a failure of one or more of the components of the normal venous system and are not mutually exclusive.

Venous obstruction causes an increased resistance to blood exiting the lower extremity. There are current data to suggest that venous occlusive disease in combination with venous insufficiency is found in 55% of patients with CVI, especially those with the most severe symptoms.¹⁵² Clearly in the past,

there existed an underestimation of the importance and prevalence of occlusive disease in the pathophysiology of CVI.¹⁵²⁻¹⁵⁴ The hemodynamic result is elevated IV pressure noted clinically as pain especially after exercise.¹⁵² If the deep system is primarily involved, the increased pressure generated with each calf compression may impact the perforating veins resulting in valvular malfunction and lead to venous hypertension in the superficial system and its capillary network. Asymptomatic primary iliac venous compression is quite common with intraluminal ($27 \pm 5\%$) and varying degrees of external compression (66% to 88%) observed in the general population.¹⁵⁵⁻¹⁶⁰ Left common iliac vein compression by the right common iliac artery, as well as external iliac vein compression from the internal iliac artery on either side, and variations thereof have been described.^{159,161} It has been suggested that the nonthrombotic iliac stenosis is a “permissive lesion” not clinically significant until other components of the lower extremity venous circulation fail.¹⁶² The good results of iliac vein stenting in patients with CVI, even in the presence of untreated reflux, demonstrate the impact that eliminating proximal obstruction has on improving overall venous hemodynamics. In one of the largest experiences treating ileofemoral venous occlusive disease involving nearly 1,000 patients, compression of the common iliac vein was seen in 36%, external iliac vein in 18%, and both sites in 46% of limbs.¹⁶² Of these patients, 53% of limbs had nonthrombotic compressive lesions (absent history of DVT, no venographic or ultrasound findings indicating previous DVT); 40% had postthrombotic obstruction; and 7% had a combined etiology. Furthermore, 20% of the patients were men and 25% of the symptomatic lower limbs were on the right side. Intraluminal webs from repetitive trauma have been reported in 14% to 30% of symptomatic cases of May–Thurner syndrome.¹⁶¹ Extrinsic compression of the iliac and pelvic veins may also be caused by tumor, fibrosis, or infection. Contents of a femoral hernia can crush the femoral vein, as can soft tissue tumors of the thigh. Arterial aneurysms can impinge on the femoral vein. The popliteal vein can be obstructed by a popliteal aneurysm or Baker cyst.¹²⁵ Aplasia of the vein or tumors of the vein wall have been described.^{125,163} DVT is associated with inflammation and thrombus resolution resulting in external vein wall scarring with stiffening and thickening, as well as intraluminal recannulation with webs and bands. The venous valves are generally incorporated in the scarring process leading to even more occlusive debris within the lumen. It is a common cause of venous occlusive disease due to its rather high prevalence and can involve any part of the venous system.

Valvular insufficiency occurs throughout the lower extremity venous systems. It has been estimated to account for 85% of symptomatic CVD cases with a 70% incidence of primarily superficial and 30% primarily deep venous insufficiency, but these observations were likely influenced by the lack of recognizing associated occlusive disease as a contributing or sole factor in the symptoms noted.^{153,154} Duplex imaging studies suggest that patients with minimal symptoms tend to have isolated superficial reflux while those with edema, skin changes, and past or present ulcers have an increasing presence of perforator and deep disease. In those with more advanced venous disease, reflux alone is observed in 80%, reflux and obstruction in 17%, and only 29% had obstructive disease alone.^{164,165} The presence of obstructive and reflux disease had the worse prognosis for the development of skin changes.¹⁶⁶ No matter the clinical stage, the superficial system is most commonly affected (90%) with GSV involvement in 70% to 80%, SSV in 15% to 20%, and nonsaphenous veins in approximately 10%. The deep veins are involved in about 30% and perforator veins in about 20%.^{164,165} Those with the most severe sequelae of venous disease have superficial reflux in 74% to 93% with 17% to 54% having only superficial disease.¹⁶⁷⁻¹⁷¹ In such patients, 50% were noted to have superficial $\pm$ perforator disease and less than 10% had isolated deep venous reflux.¹⁷⁰⁻¹⁷³ In those patients with venous ulcers, two vein systems were involved in 50% to 70% of patients, and all three systems were involved in 16% to 50% of patients. Since these duplex imaging studies mainly involve imaging of the lower extremity veins, the influence of proximal venous occlusive disease may well be underestimated. Reflux allows the transmission of high venous pressures to the lower leg when standing that cannot be relieved by exercise. Primary valvular insufficiency is rarely a consequence of congenital absence of valves.¹⁷⁴ There are predisposing genetic factors that can lead to primary disease including Klippel–Trenaunay syndrome, FOXC2 gene mutation, desmulin dysregulation, the Ehlers-Danlos syndrome, and a CADASIL gene mutation, to name a few, but these do not reflect the typical patient.^{175,176} The muscle cell dilating effect of estrogens may explain the genesis of varicose veins noted in the first trimester of pregnancy. Prolonged exposure to high venous pressures can cause vein dilation as occurs from an arteriovenous fistula or occupations requiring prolonged periods of standing. For our standard patient, venous valve prolapse (elongated, floppy valves) and defects in the vein wall that cause the valve ring to dilate results in malfunctioning valve cusps with retained valve architecture.^{177,178} Whether the vein wall changes precede valve insufficiency or the valve insufficiency causes wall distension and wall changes is less clear.^{46,175} There

are some data to suggest that sustained local venous hypertension might affect the local venous microcirculation. Roughly 50% of deep vein valvular dysfunction occurs secondary to DVT whereas the remainder appears to be of a primary etiology with a 10% to 20% variance, depending on the clinical experience being reported.^{153,179–181} Inflammation and thrombosis associated with DVT tend to cause valve scarring, whether or not recanalization is complete, leaving a damaged valve architecture in contradistinction to primary valvular insufficiency. This classic differentiation between “primary” pathology and “secondary” (or postthrombotic) pathology does not clearly exist when subjected to direct observation of the veins and valves at surgery. In fact, the two conditions can be present in the same patient as noted some 20 years ago.¹⁸² In these cases, the vein wall is thickened and/or fibrotic at the valve station or there is thickening of the valve cusps and/or intima. Pathologic study of 11 such veins demonstrated clear postthrombotic changes in 6, but phleboscrosis of a nonthrombotic origin in the remaining 5.¹⁸³ Clearly, preservation of a normal valve architecture can be explained if primary reflux and sustained high pressure on the wall are the cause of the changes noted. Another theory is that rapid resolution of acute thrombi, an event known to occur, may have allowed these valves to escape damage or the valve itself may not have been directly involved in the thrombotic process.¹⁸⁴ The fibrotic process involves only the vein wall and the valve cusps become floppy by virtue of a decrease in wall diameter resulting from a thickened, noncompliant vein wall.¹⁸³ The valve remains architecturally intact and can be repaired surgically.

There can be failure of calf muscle pump function. The pump becomes unable to generate the force needed to eject blood from the leg while standing, resulted in sustained venous hypertension. Patients with muscle disuse (e.g., paraplegia, traumatic injury, elderly or bedridden patients) may not have sufficient muscle for effective exercise. Pathologic conditions that result in muscle fibrosis (e.g., muscular dystrophy, multiple sclerosis) can destroy the calf muscle pump. Thrombus and scarring in the gastrocnemius and soleal veins can prevent blood from entering the pump resulting in a deficient volume for ejection with contraction. Calf pump function and ankle range of motion are progressively diminished with increasing severity of CVI.^{185–188} Physical conditioning improved both pump function and muscle strength in a small, RCT, demonstrating the influence the pump can have on the lower extremity.¹⁸⁹ With the exception of muscle rehabilitation, very little can be offered to patients with some of these disorders.

Regardless of the etiology, the sequelae of venous hypertension/stasis are changes observed in the lower leg skin and subcutaneous tissues, the end organ. Originally, ischemia from various causes was considered the etiology of the damage noted in the lower leg.¹⁹⁰ More recent observations suggest that far from being simply an ischemic event, the end-organ response to venous hypertension is highly dynamic. The final answer is likely to involve a complex interaction of multiple factors that favor either continued destruction or the ultimate healing of the ulcer. Leukocytes, the extracellular matrix, fibroblasts, and a host of other factors are recruited to heal the early endothelial injury and the more delayed soft tissue injury.¹⁹⁰ In fact, current belief holds that the fundamental basis for CVD and ulceration is inflammation within the venous microcirculation when subjected to increased hydrostatic pressure.¹⁹¹ The soft tissue injury may result in a chronic ulcer that requires growth factors to force the process to healing.¹⁹² Research remains active in this component of venous pathophysiology. An excellent review is available for further information on the current understanding of basis venous pathophysiology.¹⁹³

Clinical Signs and Symptoms

Venous disease presents in many ways. A telangiectasia, spider vein, is a confluence of dilated intradermal venules less than 1 mm in caliber. A reticular vein is a dilated bluish subdermal vein, usually 1 mm to less than 3 mm in diameter and usually tortuous. These venous abnormalities may or may not be accompanied by a larger, more deeply located, pathologic vein.

Hereditary varicose veins usually appear during the second decade of life. If the varicosities are due to a secondary etiology (e.g., thrombosis, trauma), they often present several years after the inciting event. These veins appear alone or in clusters as dilated, often bluish, serpentine, and palpable protrusions of branches of the GSV, SSV, or collateral veins lying beneath the skin within the subcutaneous tissues. Varicose veins generally measure 3 or more millimeters in diameter when measured in the upright position.¹⁹⁴ One finding thought to be an early sign of advanced disease is corona phlebectatica that is a fan-shaped pattern of small intradermal veins located around the ankle or dorsal foot (also called ankle flare or malleolar flare).^{126,194} If the varicose veins observed are the result of proximal disease, such as pelvic reflux or obstruction; the location of the varicosities may be scrotal,

perineal, vulvar or posterior/lateral in the lower extremity.¹²⁶

Symptoms may be those associated with any type of CVD and are described as pain, edema, hyperpigmentation, stasis dermatitis or eczema, and/or venous ulcers. These changes often occur in the “gaiter” area just above the medial malleolus. Important perforating veins lay in this area. The observed hyperpigmentation is thought to result from extruded red blood cells that are degraded by macrophages leaving hemosiderin deposits. Less definable but described symptoms of CVD include tingling, burning, muscle cramping, a sensation of throbbing or heaviness, itching, restless or tiredness of the legs, and fatigue.¹⁹⁵ They are more specific indicators of venous disease if made worse with standing and heat and if relieved by rest and leg elevation.

Venous claudication is a pain syndrome experienced when walking and is associated with cyanosis, a sensation of increased swelling, and increased prominence of the superficial veins, which is relieved with rest in combination with elevation of the extremity.^{152,196,197} It may be so severe in rare cases that amputation is requested.¹⁹⁸ The most severe form is observed when venous incompetence is associated with obstruction and when the obstructive process is in a more proximal locale.¹⁹⁹

4 Critical to patient management and treatment evaluation is an accurate classification of the disease at any given time. Each patient should be stratified according to the clinical picture, the etiology, the anatomic distribution, and the pathophysiology (CEAP) classification system (Table 98-2).²⁰⁰ This classification system helps the physician define the venous disease so that a focused and appropriate management strategy can be formulated. An extension of the clinical classification system, the Venous Clinical Severity Score, is available to quantify the extent of venous disease and, therefore, to evaluate the patient’s clinical response to treatment (Table 98-3).^{201–203} The anatomic and pathophysiologic improvement following a treatment of venous disease can be scored using the Venous Segmental Disease Score.²⁰² While the Venous Disability Score provides some information of what a person can do while afflicted with venous disease.²⁰² QOL surveys have been developed specifically for patients with venous disease to help determine the impact of the disease on the patient’s life and the effect therapy has on the patient’s overall well-being.^{126,193,204–208} Consistent application of these surveys to the pre- and postsurgical outcome of patients has yet to be achieved but is imperative to improve our ability to precisely determine the effect and benefit of a given intervention.

CLASSIFICATION

Table 98-2 Clinical Classification of Chronic Venous Disease

Class	Description
0	No visible or palpable signs of venous disease
1	Telangiectasias and/or reticular veins
2	Varicose veins
3	Edema
4a	Skin changes (pigmentation and/or eczema)
4b	Skin changes (lipodermatosclerosis and/or atrophie blanche)
5	Healed venous ulcer
6	Active venous ulcer
S (in addition to the class)	Symptoms including ache, pain, tightness, skin irritation, heaviness, muscle cramps as well as other complaints attributable to venous dysfunction
A (in addition to the class)	Asymptomatic

Diagnostic Evaluation

The diagnosis of CVD begins with a thorough history and physical examination. The history is quite important to provide hints to familial coagulation disorders or events in the patient’s history that may impact the care of this chronic disorder. Prior DVT, pregnancies, a family history of varicosities, obesity, or the presence of other factors associated with CDV will add support to the presence of venous disease. When performing physical examination, the location, distribution and size of varicosities, skin changes, and/or presence or indication of past ulcers should be noted. Swelling should be quantified, the location specified, and a determination made whether it is pitting or nonpitting in nature. Inspection, palpation, and auscultation (presence of a bruit) may be keys to the presence of a vascular

malformation or arteriovenous fistula. Utilization of the CEAP clinical classification (Table 98-2) will provide a snapshot of the patient being examined, whereas the use of the more detailed Venous Clinical Severity Score (Table 98-3) will allow some impression of how any therapy is performing as the patient is being treated.

In addition to determining and classifying the signs and symptoms of venous disease, the history and physical examination should exclude other potential etiologies for the patient's complaints such as arterial occlusive disease, collagen vascular disorders, allergic reactions, infection, or malignancy. Appropriate confirmatory diagnostic studies may be required to confirm the clinical suspicion, such as a lower extremity arterial Doppler study, biopsy, or specific laboratory studies when the diagnosis is unclear. Such studies become most pertinent during the evaluation of advanced venous disease, especially venous ulcers.¹⁹³ Only in select patients, such as those with recurrent, early, or unusual sites of DVT or recurrent venous ulcers, evaluation for thrombophilia is recommended.^{126,193}

Venous duplex ultrasonography provides a B-mode picture of the vein, as well as spectral analysis of the blood flow within, and is recommended as the first diagnostic test for all patients with suspected CVD.²⁰⁹ To provide an accurate impression of the venous disease present, a standard technique is followed and has been outlined in a current review article.¹²⁶ Venous duplex imaging clearly visualizes deep, superficial, and perforator veins and often the valves that lie within the veins. The venous duplex study can help to clarify the etiology (E of CEAP; congenital, primary, or secondary), better define the anatomic location (A of CEAP; specific veins can be imaged with spectral analysis to determine reflux), and aid in determining the pathophysiology (P of CEAP; reflux, obstruction, or both) of the venous problem. Once considered unnecessary in the evaluation of patients with simple varicose veins, it has become common practice prior to intervention for superficial reflux due to anatomic variability and the need for precise targeting of veins during endoluminal intervention.^{121,210-212}

DIAGNOSIS

Table 98-3 Venous Clinical Severity Score

Attribute	Absent 0	Mild 1	Moderate 2	Severe 3
Pain	None	Occasional, not restricting activity or requiring analgesics	Daily, moderate activity limitation, occasional analgesics	Daily, severe limiting activities, regular use of analgesics
Varicose veins ^a	None	Few, scattered: branch VVs with competent GS/SS	Multiple: single-segment GS/SS reflux	Extensive: multisegment GS/SS reflux
Venous edema ^b	None	Evening ankle edema only	Afternoon edema, above ankle	Morning edema above ankle and requiring activity change, elevation
Skin pigmentation ^c	None or focal, low intensity (tan)	Diffuse, but limited in area and old (brown)	Diffuse over gaiter distribution (lower 1/3) or recent pigmentation (purple)	Wider distribution (above lower 1/3) and recent pigmentation
Inflammation	None	Mild cellulitis, limited to marginal area around ulcer	Moderate cellulitis, involves most of gaiter area	Severe cellulitis (lower 1/3 and above) or venous eczema
Induration	None	Focal, circumalleolar (<5 cm)	Medial or lateral, less than lower third	Entire lower third of leg or more
No. of active ulcers	0	1	2-4	>4
Active ulceration, duration	None	<3 mo	>3 mo and <1 y	Not healed >1 yr
Active ulcer, size ^d	None	<2-cm diameter	2- to 4-cm diameter	>4-cm diameter
Compressive therapy ^e	Not used or not compliant	Intermittent use of stockings	Wears elastic stockings most days	Full compliance: stockings + elevation

^aVaricose veins must be >4-mm diameter to qualify so that differentiation is ensured between C1 and C2 venous pathology. Occasional or mild edema and focal pigmentation over varicose veins does not qualify for C3 or C4.

^bPresumes venous origin by characteristics (e.g., brawny [not pitting or spongy] edema), with significant effect of standing/limb elevation and/or other clinical evidence of venous etiology (i.e., varicose veins, history of DVT). Edema must be regular finding (e.g., daily occurrence). Occasional or mild edema does not qualify.

^cFocal pigmentation over varicose veins does not qualify.

^dLargest dimension/diameter of largest ulcer.

^eSliding scale to adjust for background differences in the use of compressive therapy.

GS, Greater saphenous; SS, small saphenous; VV, varicose vein.

From Rutherford RB, Padberg FT Jr, Comerota AJ, et al. Venous severity scoring: an adjunct to venous outcome assessment. *J Vasc Surg* 2000;31:1307.

Valvular insufficiency is defined as prolonged reflux time through a valve following a provocative test when duplex imaging is the diagnostic modality. To aid in the standardization of the test, rapidly deflating distal cuff technique is used in some vascular laboratories, while others use manual compression of the distal leg after which valve reflux is determined during duplex imaging.^{132,133} An

abnormal reverse venous flow (reflux) in the saphenous, tibial, and deep femoral veins is 0.5 seconds or greater while the femoral and popliteal veins have a cutoff value of 1 second ²¹³ Since perforating vein reflux can also be associated with venous pathology, significant work has gone into determining how to define abnormal reflux. Current consensus and available data suggest that a “pathologic” perforating vein is defined as a vein with an outward flow of ≥ 0.5 seconds, with a diameter of > 3.5 mm, which is located beneath a healed or open venous ulcer.^{126,209,212,213} The duplex examination for reflux is performed in the upright position in these reports. Many other provocative maneuvers to generate venous reflux exist (Valsalva, standardized Valsalva, etc.) in addition to performing the test in different positions (e.g., 15° Trendelenburg, sitting) and are used in many laboratories for particular patients who have difficulty standing.²¹⁴ Each may be acceptable if standardized for an individual laboratory. Venous obstruction is seen as thickened, scarred, and constricted veins with poor flow and diminished augmentation following distal and/or proximal compression. Respiratory variation is lost as a result of local occlusive disease or proximal occlusion. Disease within the SSV should not be ignored because it can have a significant clinical impact as an isolated finding.²¹⁵ By imaging the entire lower leg venous system, the surgeon is provided a detailed roadmap of all veins with determination of obstruction or reflux within segments separated by valves. Isolated venous valvular insufficiency or obstruction may have little clinical impact on the patient, and therefore clinicians have attempted to quantify the pathology by adding up segmental disease, determining mean duration of reflux, determining peak reverse flow velocity, and so forth.^{133,198} Although average scores correlate with disease severity, individual results have little predictive value and, therefore, these methods have not been widely adapted. This is often the only diagnostic tool needed for the evaluation of superficial and even perforator disease requiring treatment as a first stage in patient management.

A difficult area of investigation from a noninvasive perspective is the pelvic, abdominal, and chest veins. CT and MRI can provide details of anatomy and the effect of surrounding structures in areas not visualized by duplex evaluation.^{193,216–219} These studies can be particularly useful in evaluating for pelvic congestion syndrome.²²⁰ However, as with all vascular laboratory studies, clinical correlation is mandatory because anatomic presence does not necessarily translate into a clinical problem. For example, iliac vein compression is commonly seen in an asymptomatic population.^{155–160}

Plethysmography assesses the overall hemodynamics of the lower extremity venous system. Air plethysmography (APG) can measure several venous hemodynamic parameters. A plastic cylinder filled with air is fitted over the calf and foot and changes in leg volume with positional change or exercise are detected by pressure changes in the cylinder. The venous filling index is 90% of resting standing VV divided by the time it takes to reach 90% of VV as the patient shifts from the supine to standing position (mL/second). A venous filling index of 2 mL/second or less is indicative of competent venous system and higher values suggest venous insufficiency.^{221,222} After an erect baseline reading, patients exercise by dorsiflexion or heel raises to empty the calf veins. The ejection fraction is the amount of blood propelled cephalad with a single muscle contraction divided by VV. After a series of 10 ankle flexions, the volume remaining in the leg is referred to as the residual volume and, when divided by the VV, is called the residual volume fraction. An ejection fraction of greater than 60% and residual volume fraction of less than 35% suggest that the calf pump is working well.^{187,223} The residual volume fraction is relatively equivalent to the AVP.^{142,224} Significant outflow obstruction is determined by occluding venous outflow until a stable plateau is reached. The thigh cuff causing the venous occlusion is rapidly deflated, and the difference between maximal volume and that volume present 1 second later divided by the total calf volume is called the outflow fraction. Normally, 38% or more of venous blood is expelled from the leg in 1 second.²²² Several other plethysmographic methods (e.g., impedance, photo) and even light reflex rheography have evaluated similar venous parameters. The accuracy of these techniques to reliably eliminate the presence of significant venous occlusive disease is poor.²²⁵ Although these plethysmographic methods can differentiate patients with severe CVI (class 3 or greater) from those without disease, stratification by symptom severity is not possible and, therefore, its use in the treatment of patients with minor symptoms, such as varicose veins or telangiectasias, is also questionable.²¹⁴ In current clinical practice, it is being used only in complex cases or for research purposes. Current consensus encourages the use of plethysmography in the patient with advanced CVD if duplex scanning cannot provide a definitive diagnosis often underlying pathophysiology.¹²⁶

As in acute venous disease, venography has no significant role in the initial evaluation of patients with CVD. Ascending venography can suggest venous occlusion when duplex imaging clearly demonstrates an open system.²²⁶ Even the presence of significant collaterals on transfemoral venography may underestimate the degree of venous occlusion as documented by intravascular

ultrasound.^{152,227} The use of ascending venography is selectively used in specific cases to complement noninvasive studies when considering intervention in the deep venous system or in research protocols.

The technique of descending venography has been well described.²²⁸ Descending venography is used to determine valve leaflet integrity and anatomic location and demonstrate the extent of reflux.²²⁸ Assessment of the competence of the profunda femoris venous system in addition to the femoral system is imperative. If it is a competent system, it may be a source for a valve transposition or may predict success with an isolated proximal femoral vein repair.^{229–231} Certainly, descending venography is not infallible in determining the presence or absence of a normal valve.¹⁸³ Raju et al.¹⁸³ report that descending venography misrepresented the presence of a valve in 11% of cases (a valve considered present was not at operation) and missed an intact valve in 25% of cases (a valve thought absent was actually present). However, when combined with a careful venous duplex examination, it is currently the best method available to determine preoperatively if an in situ reconstruction will be possible.

Intravenous pressure measurements can aid in the diagnosis of venous disease but is invasive and generally used only when invasive surgery of the deep system is being considered. This study can help to determine the overall magnitude of reflux and can be correlated with the incidence of venous ulceration.^{142,232} Direct lower limb IV pressure measurements before and after reactive hyperemia and when compared to arm IV pressure has not consistently determined the significance of proximal venous occlusive disease such that the authors of this technique now recommend IV ultrasonography as a more reliable diagnostic tool.²²⁵ Although IV pressure measurements and venography were once the gold standard for evaluating venous disease, duplex scanning with the addition of intravascular ultrasonographic techniques when required is the anatomic and functional test of choice in current medical practice.

Treatment Options and Results

Medical Therapy

Compression has been the mainstay of the medical treatment for all stages of CVI for centuries. The goals are to manage clinical symptoms and to control venous hypertension. Roughly speaking, there are two types of compression: elastic (e.g., support stockings or long stretch bandages) and inelastic (e.g. Unna's paste boot, short stretch bandages, multilayer [four-layer] bandage, or Velcro band devices). A graduated compression stocking is a single-layer elastic compression often used to control edema. The term *multilayer* when dealing with compression denotes a bandage that covers the leg with more than one layer because of overlapping during placement. The term *multicomponent* is a multilayer bandage with several components, such as an Unna's boot, underlying paste layer covered by an elastic wrap. In general, the more layers the less elastic and more stiff the compression. The degree to which any particular bandaging is one or the other will depend on the care provider who applies the compression along with other factors. The mechanical effect is dependent on the level and type of compression and the desired amount of compression is influenced by the underlying venous pathology being treated. Initial narrowing of deep and superficial calf veins on standing as determined by duplex imaging is observed at 20 mm Hg with improved venous hemodynamics and improved QOL data when used to treat mild disease.^{233–237} Consistent narrowing of superficial and calf veins occurs at a median of 30 to 40 mm Hg pressure on standing while complete occlusion occurs at a median pressure of 70 mm Hg. Complete occlusion is not the goal. Therapeutic calf compression improves calf muscle pump function expressed as a reduction in residual volume fraction during walking.²³⁸ Duplex imaging has demonstrated that thigh compression was helpful in reducing great saphenous and femoral vein diameter at a constant pressure of ≥ 40 mm Hg and reduced venous reflux (by APG) at 60 mm Hg.²³⁹ Overall, these effects on the underlying veins help to improve the venous pump and decrease the VV in the lower extremity. It is interesting that elastic stocking maintain a rather constant pressure during exercise and at rest. Alternatively, inelastic wraps demonstrate a more dramatic increase in pressure during exercise since they do not stretch but have decreasing pressure with recumbence as the edema exits the leg and the bandage maintains its shape.²⁴⁰ This difference in performance helps to explain why inelastic wraps are much better tolerated when left on for days and especially at night when the constant compression is not required and may be perceived as discomfort. It also explains why compression should be changed more frequently early in treatment and less frequent latter as the degree of edema requiring control lessens.

Although there has been concern that compression may impede microcirculatory flow and thereby jeopardize tissue viability,²⁴¹ it is known that compression, when used to treat edema, has a positive influence on the local skin and soft tissues by improving capillary filtration rate, decreasing the

subcutaneous pressure in the perimalleolar area, promoting extracellular fluid reabsorption, and improving sodium subcutaneous tissue clearance.^{242,243,244} Compression improves skin transcutaneous oxygen tension and skin capillary density in patients with venous insufficiency.^{245,246} Compression can increase microcirculatory flow velocity and ameliorate the inflammatory injury and fibrosis associated with CVI.^{240,245,247,248} Cytokines, such as vascular endothelial growth factor and tumor necrosis factor, decrease with compression therapy and correlate with ulcer healing.²⁴⁹ Furthermore and in contradistinction to the first statement in this paragraph, standard compression can actually increase arterial blood flow in some circumstances.^{240,250} The lymphatic system is often involved in the overall pathophysiologic state of patients afflicted with venous insufficiency and performance of this outflow system is improved with compression.²⁴⁶ In patients with concomitant arterial occlusive disease with an ankle to brachial systolic blood pressure ratio (ABI) of 0.80 or greater, the use of standard compression is safe and effective and actually increases arterial perfusion in affected tissues.^{251–253}

In those with more advanced arterial occlusive disease defined as an ABI ≥ 0.50 (but < 0.80) or an ankle systolic pressure ≥ 60 mm Hg or toe pressure ≥ 30 mm Hg as a minimum; modified compression dressings with lower pressure ratings not to exceed the tissue perfusion pressure can improve tissue perfusion and aid in healing ulcers of mixed etiology.^{253–255} These data support the current SVS/AVF practice guideline that suggests that in a patient with a venous leg ulcer and underlying arterial disease, compression bandages or stockings **are not indicated** if ABI is 0.5 or less or if the absolute ankle pressure is less than 60 mm Hg.¹⁹³

Evidence-based medicine confirms our clinical impression and basic science findings regarding the potential benefits of compression garments for the treatment of CVI. Substantial evidence exists to demonstrate that compression is statistically beneficial for most clinical stages of symptomatic venous disease (C_{2–6}). A recent large systematic review evaluating the use of compression for varicose veins (C₂) demonstrated that symptoms were improved, but the analysis could not confirm that its use decreased progression of disease or prevented recurrence after invasive treatments.²⁵⁶ Whether compression stockings should be the primary treatment for symptomatic varicose veins has been challenged by the recent RCT titled the Randomized Clinical Trial, Observational Study and Assessment of Cost-Effectiveness of the Treatment of Varicose Veins (REACTIV) trial.²⁵⁷ This study randomized 246 patients with class C₂ disease into conservative management including compression versus high ligation, stripping, and phlebectomy. Over the span of a 2-year follow-up, there was a statistically significant benefit from surgery in quality-adjusted life-years when analyzed by two scoring systems in addition to improvements in symptomatic and anatomic measurements. Cost-effective analysis demonstrated a benefit for the surgical intervention as well. Therefore, in contradistinction to current third-payer policies, and based on available statistical data, the SVS/AVF Guidelines Committee recommends against compression therapy being considered the primary treatment of symptomatic varicose veins in those patients who are candidates for saphenous vein ablation as a grade 1B recommendation.¹²⁶ Certainly in those not candidates or those who do not desire interventional options, the Guidelines Committee suggests compression therapy (20 to 30 mm Hg) for symptomatic benefits (grade 2C).

Compression is the standard of care for patients with advanced CVD (C_{3–6}) and the majority of the evidence-based data investigate the benefits of treating venous ulcers since the rate and degree of healing are measurable. The SVS/AVF commissioned a comparative systematic review and meta-analysis of compression modalities and venous ulcer healing.²⁵⁸ Nine RCTs provided objective data on initial ulcer size and outcomes as measured by time to complete healing or proportion of ulcers healed. The evidence suggests that venous ulcers heal more quickly with compression therapy than without compression. Most RCTs demonstrated a benefit in healing rate with various compression methods used.^{259–261} In addition, the SVS/AVF commissioned analysis of compression and venous ulcer healing demonstrated low-quality evidence to support the effect of compression on ulcer recurrence.²⁵⁸ Compliance with compression is a challenge for patients with chronic disease and noncompliance is associated with recurrence while the ability to maintain compression demonstrated less recurrence in most studies.^{262–264} Compression comes in many forms and is a factor in venous ulcer healing potential. The SVS/AVF commissioned analysis found moderate-quality evidence to support multicomponent compression over single component compression to treat venous ulcers.²⁵⁸ The best studies evaluated a multilayer (four-layer) bandage versus a single-layer bandage and demonstrated improving overall healing rates with faster closure rates.^{265,266}

However, the skill of those applying the single-layer dressing might improve these results to mimic the multilayer compression.²⁶⁷ These data have led the SVS/AVF Guidelines Committee to recommend that compression be used to heal venous ulcers (grade 1A), to decrease recurrence (grade 2B), and it is

suggested that multicomponent compression bandages be used to treat venous ulcers (grade 2B).¹²⁶

One last comment on the use of compression in the treatment of venous ulcers, although surgical intervention is suggested over the use of compression alone to heal venous ulcers, post-interventional compression does help to prevent recurrence. This has been demonstrated in two RCTs and in the SVS/AVF commissioned comparative systematic review and meta-analysis of surgical interventions versus conservative therapy for venous ulcer treatment.^{268–270}

In the final analysis, multilayer relatively inelastic wraps are preferred for the therapy phase of venous disease (ulcer healing). When the ulcers are healed, elastic wraps, such as compression stockings, are used to maintain a stable clinical condition (maintenance phase). In addition, elevating the legs when possible during the day, avoiding prolonged periods of standing or sitting, and elevating the foot of the bed 4 to 6 in above the heart while sleeping are adjuvant components of conservative therapy.^{271,272}

Intermittent pneumatic compression (IPC) provides pulsatile emptying of the venous system via compressive bladder(s) that inflate and deflate. Some data suggest a positive impact on the inflammatory injury and associate fibrosis when IPC is used to treat CVI.^{240,247} A Cochrane review suggests that there is advantage in using IPC compared to no compression, but there is little evidence to suggest that the addition of IPC to compression therapy is beneficial.²⁷³ Certainly, one RCT of 45 patients has demonstrated its use in patients with long-standing ulcers (at least 3 months' duration) comparing standard ambulatory compression with or without the addition of IPC. At 3 months, 10 of 21 ulcers healed with the addition of IPC, while only 1 of 24 healed with standard care.²⁷⁴ One study suggests that a rapid cycle method improves ulcer healing compared with a slow cycling regimen.²⁷⁵ This data is the basis for a practice guideline, suggesting that IPC be employed when compression has failed, is unavailable, or cannot be used.²⁷⁶

Lifestyle changes, including exercise, improved mobility, and foot exercises, can aid in lowering the incidence of venous ulcer recurrence as demonstrated by a recent literature review.²⁷⁷ Structured exercise can improve dynamic muscle strength and calf muscle pump function in patients with essentially all levels of CVI from varicose veins to venous ulceration.^{189,278,279} It is unclear whether such exercise improves ulcer healing rates per se. The use of supervised active exercise to improve muscle pump function and to reduce pain and edema in patients with leg ulcers is a guideline recommendation (grade 2B).²⁷⁶ In Europe and other countries, various oral agents (e.g., diosmin, rutosides) have been touted to improve the feeling of heaviness, fatigue, and even edema of CVD but these agents are not available in the United States.^{126,276} A Cochrane review selected 44 studies of such agents for meta-analysis and concluded that there was insufficient evidence to support the global use of these drugs in the treatment of CVD.²⁸⁰ Drugs potentially useful in treating patients with venous ulcers are available in the United States. Pentoxifylline does provide an incremental benefit in ulcer healing and has an improved outcome with higher doses but the trade-off is more gastrointestinal adverse effects.^{265,281–283} For long-term effects and as an adjunct to compressive therapy when standing or large venous ulcers, pentoxifylline, in combination with compression therapy, is recommended (grade 1B).²⁷⁶ Current practice is to prescribe 400 mg of pentoxifylline three times per day and, if tolerated, the higher dose is 800 mg three times per day. Prophylactic use of systemic antibiotics in the treatment of venous ulcers is not recommended and may only select resistant organisms. One randomized clinical trial in 47 patients compared elastic support bandages only versus those also treated with systemic antibiotics. There was no statistical difference in healing rates of ulcers or in changes of the microbiologic flora.²⁸⁴ Clinically, evident disease with supportive quantitative wound cultures has demonstrated beneficial effects when systemic antibiotics are used, but the data are meager.²⁸⁵ Certainly, an established infection (cellulitis or deeper) must be treated as it would be at any site and is recommended best care by the SVS/AVF Guidelines Committee. In addition, the recommendation is for oral agent use for 2 weeks unless evidence of clinical infection continues (grade 1C).²⁷⁶ Limb cellulitis with or without a venous ulcer generally requires systemic gram-positive antibiotic coverage as demonstrated by several studies and is a grade 1B recommendation for patient care.^{276,286}

Surgical Therapy

The use of surgical intervention in the realm of venous disease as in all areas of vascular surgery is driven by the documented presence of disease, the risk of the intervention planned, and the expected outcome ([Algorithm 98-1](#)).

Telangiectasia, Reticular Veins, and Branch Varicose Veins. Percutaneous laser energy (a lamp that produces laser light that is shined on the blemish) can be used to treat telangiectasias up to 0.7 mm

in diameter with reasonable success. For matting and telangiectasias under 0.5-mm diameter, the flashlamp pumped dye laser (595-nm wavelength) is well studied.²⁸⁷ The potassium titanyl phosphate (KTP) laser of wavelength 532 nm is applicable to those 0.7 mm or less.²⁸⁸ Since melanin is the prime competing light absorber to hemoglobin in the body, the increased epidermal melanin in the tanned skin risks long-lasting hyperpigmentation and, therefore, percutaneous laser therapy should not be performed in those with a sun-tan.

Sclerotherapy (needle injection of caustic solutions directly into superficial veins with or without fluoroscopic guidance) has long been advocated for treating varicosities remaining after saphenous ablation, small isolated varicosities, telangiectasias, and reticular veins.^{289–291} Sclerotherapy alone appears an effective treatment for branch varicosities in patients without major saphenous reflux and appears effective when combined with GSV ablation to control branch varicosities.^{292–294} The FDA-approved sclerosing agents are sodium tetradecyl sulfate, sodium morrhuate, polidocanol, and glycerine. Hypertonic saline (23.4%), although not approved for sclerotherapy in the United States, has been used for many years. Polidocanol used extensively in Europe is now commercially available in the United States and has rapidly been adopted as the workhorse for venous sclerotherapy because of very low allergic and anaphylactic reaction rates while being essentially painless with a low risk of tissue necrosis. All act to damage the vein endothelium-inducing inflammation and scarring with ultimate lumen collapse.^{289,295} Foam sclerotherapy is the addition of air or other gases, such as carbon dioxide, to liquid sclerosing agents, particularly detergent sclerosants, to allow a more protracted contact of the sclerosing agent to the vein wall. This modification adds a component to the agent that converts its use to off-label. The most popular technique uses two syringes and a three-way stopcock to allow the gas to be aspirated into one of the syringes, while the other syringe contains a detergent sclerosant, which results in a 1 part of drug to 4/5 parts of gas. Pushing the mixture from one syringe to the next 20 times results in desired bubble size.²⁹⁶ This technique is favored by many phlebologists especially for the treatment of larger veins, such as the saphenous vein.^{292,297} Leg elevation is often employed to decrease the risk of systemic embolization during injection. The exact concentration of sclerosant, liquid or foam, used for sclerotherapy is dependent on vein size and agent used.^{289,295} These interventions are generally outpatient procedures. Burning, stinging, itching, and muscle spasm are commonly observed with sclerotherapy injections.^{298–300} Extravasation of the agent can cause fat or skin necrosis, ulcerations, and/or hyperpigmentation of the surrounding skin.^{298,300} Posttreatment veins are often a brown color as opposed to the blue-red pretreatment color. Microthrombectomy of clotted blood trapped in treated veins appears to reduce postsclerotherapy pigmentation especially in veins 1 mm or less in diameter.³⁰¹ Other potential complications of sclerotherapy include allergic reactions and toxicity if too much agent is used at one sitting.^{289,298,300} Therefore, a limited amount of sclerosing agent is typically injected during a single setting. Rarely ocular events or even cerebrovascular events have been observed following foam sclerotherapy and, therefore, must be discussed with the patient prior to its use.^{299,302} The thought is that the sclerosing agent gets into the systemic circulation and potentially even the eye or brain. The presence of a patent foramen ovale is associated with a higher frequency of transient neurologic events.³⁰³ The use of CO₂ as the mixing gas used for foam sclerotherapy appears to decrease the risk of such adverse events.³⁰² On the basis of the available data, the SVS/AVF Guidelines Committee recommends that liquid or foam sclerotherapy be used to treat telangiectasia, reticular veins, and varicose veins (grade 1B).¹²⁶

Algorithm 98-1

Algorithm 98-1. Treatment of chronic venous insufficiency.

Phlebectomy (ambulatory phlebectomy, stab avulsion, stab phlebectomy, microphlebectomy, and microextraction are synonymous terms) is a technique in which varicose veins are removed through small stab incisions with hooks or small mosquito clamps used to pull the vein from its bed. There are a number of phlebectomy instruments available.³⁰⁴ It can be performed in an ambulatory setting with local anesthesia or in conjunction with a more invasive procedure. One small randomized controlled study suggests that this approach may have improved results over sclerotherapy.³⁰⁵ Which approach is best remains a point of contention in the literature and is often physician choice. Complications are generally minor and of low risk (<2%), including development of telangiectasia, blistering, hyperpigmentation, and missed varix.³⁰⁶ Tumescence anesthesia has allowed for extensive interventions with little pain and on an ambulatory basis.³⁰⁷ Such field anesthesia allows for another method of phlebectomy, powered phlebectomy, involving a modified arthroscopic shaver with transillumination that allows venous clusters to be illuminated, morcellized, and aspirated. When compared to ambulatory phlebectomy, there is no benefit in patient cosmetic scores or satisfaction and the recurrence rate at 1 year is 15% higher.³⁰⁸ The added cost and lack of patient preference will likely prevent this technique from becoming widely adopted.

Saphenous Vein Stripping/Ablation. Saphenous preservation can lead to good results in the hands of very skilled interventionalist willing to interpret detailed preoperative imaging (proper patient selection) and a detailed technical approach.³⁰⁹⁻³¹¹ It involves removal of only selected branch varicosities resulting in improved saphenous function or at least preservation of the saphenous vein without an unacceptable rate of recurrent varicosities over time. Because of the technical demands and limited data available to compare results with more standard treatments, treating saphenous veins reflux and associated varicose veins with such techniques is only suggested as appropriate in the hands of skilled interventionalists (grade 2B/C) by the SVS/AVF Guidelines Committee.¹²⁶

If widespread saphenous insufficiency is present, some method of eliminating reflux is required for best results. Entirely removing the refluxing vein from the venous system is the current best and most studied solution. The vein can be stripped from its bed and discarded. The procedure is called saphenous vein high ligation and stripping. Lower leg deep venous occlusive disease is not an absolute contraindication to removal of the saphenous system and may actually be indicated in patients with mixed obstruction/reflux disease and is often the first step in cases of combined deep and superficial insufficiency.^{312,313} Preoperatively, with the patient standing to fully dilate the veins, the varicosities are marked with a permanent marker for later operative visualization. The operation includes ligation and disconnection of the GSV at the SFJ via open incision followed by complete removal of the vein to the knee by one or more distal incisions centered over the vein. If the below-knee greater saphenous

vein is incompetent based on preoperative diagnostic studies, it may also be excised. The method of vein removal may involve the introduction of long metal or plastic stripping wires with removable heads of varying size or various other devices aimed at pulling the vein from the leg.^{314,315} There is even a long probe that is placed down the saphenous after cephalad exposure and to the caudal area of desired vein removal that, when activated, freezes the vein to the probe that is then pulled from the leg with the vein attached (cryostripping).³¹⁶ Both GSV and SSV can be treated by these methods taking into account required patient positioning and anatomic variability especially of concern in the case of the SSV.³¹⁴ In particular, protection of the sural nerve by limited deep dissection is helpful. Among properly selected patients undergoing GSV high ligation and stripping, recurrent saphenous varicosities will be noted in less than 25% of cases at 2 years but increases to 41% at 5 years and 62% at 11 years, depending on the rigor of patient evaluation.^{315,317,318} These results serve to highlight the chronicity of varicose vein disease and place in perspective the expectations for other forms of saphenous ablation. With the addition of new ablation technology, this approach to saphenous insufficiency has been largely replaced in the United States, but certainly not so in less wealthy healthcare systems throughout the world.

A more recent advancement that allows the saphenous vein to be removed from the venous circulation without being extracted from the body is called endovenous thermal ablation. It uses a variety of devices to ablate (burn) and permanently scar the vein such that it does not act as the conduit for venous blood (therefore no reflux of blood can take place). The two most common methods use radiofrequency-generated heat^{319,320} or a laser fiber (with or without cap) that generates heat to cause a thermal injury to the vein.³²¹⁻³²³ Placed percutaneously or rarely by venous cut down, the respective probe is advanced into the vein to about 2 cm below the junction with the deep vein and sequentially heated throughout the length of the GSV as it is pulled back to the entrance site. Tumescence anesthesia is administered within the saphenous compartment providing anesthesia, a heat sink, and some venous compression during the procedure. The precise parameters for heating the radiofrequency ablation (RFA) probe is standardized for each pullback length (7 cm) at 120 degrees for each 20-second cycle with two treatment cycles used in the more proximal segment of the vein. The time for ablation is significantly decreased from the original device that involved a slow pull-back process and at 6 months this new technique was effective demonstrating 99.6% of veins remaining ablated.³²⁴ This data mimics the results of the older technique which demonstrated results comparable and, in some respects, superior to open surgery.³²⁵⁻³²⁹ Laser energy of various wavelengths (810 to 1,470 nm) delivered via bare-tipped fiber will cause a localized thermal injury to the vein wall.³²¹⁻³²³ The laser probe technique is more physician directed and involves a pullback of 1 to 2 mm/second for the first 10 cm and then 2 to 3 mm/second for the remaining vein length to deliver a 50 to 80 joules/cm when using the 810-nm diode laser. This technique rivals RFA and surgery results in the treatment of saphenous vein reflux.³³⁰⁻³³⁵ Several other innovative methods of ablating the saphenous vein include, but are not limited to, steam, pharmacomechanical methods, cyanoacrylate plugs, and likely others to come which still require study to determine how each will fit into our interventional armamentarium.

Hamel-Desnos et al.²⁹⁷ found GSV ultrasonography directed foam sclerotherapy to be 84% effective in eliminating reflux for 1 year. Midterm results in 175 patients reported a 2-year primary success rate of 55% with a 77% secondary success rate in preventing recurrent reflux.³³⁶ The long-term results of the VEDICO trial would suggest that substantially more veins are present at 10 years when foam is used as a single modality than when surgery or surgery and foam are used.²⁹² If recurrence without reintervention is the goal, sclerotherapy appears to be at a disadvantage. Meta-analysis would suggest that over time sclerotherapy loses its advantage to other more long-lasting interventions as would select individual experiences.^{289,292,293,297,337,338} Newer techniques of sclerotherapy lack long-term evaluation.

Complications of GSV surgery are rare but include wound infection, DVT, nerve damage, and hematoma formation to mention the most common.^{317,339,340} Saphenous nerve injury can result in an area of numbness around the knee or foot but is often clinically irrelevant.^{119,138} Complications from SSV stripping are also typically rare but include bleeding, hematoma formation, sural nerve damage, DVT, and wound infection.³⁴¹ These same complications are reported for radiofrequency and laser ablations possibly at a slightly lower incidence for some, such as nerve paresthesia. DVT risk is about 1% for all procedures.^{317,320,323,339,340,342} A complication unique to the radiofrequency and laser procedures is thermal damage to adjacent structures, such as nerve or skin, that appear to be mitigated by tumescence anesthesia.³¹⁹ Complications as well as short- and midterm freedom from recurrence for both radiofrequency and laser saphenous vein ablation compare favorably with standard stripping and both may provide patient benefit.^{320,323,342}

5 Based on the previous data in addition to other publications, which can be found in a recent meta-analysis sponsored by the SVS and AVF and a consensus document, the following guidelines have been proposed regarding the treatment of C₂ (patients with varicose veins) to improve QOL and to prevent recurrence.³⁴³ High ligation and stripping of the GSV to the knee are suggested for incompetent GSVs (grade 2B) with a 1-week period of postoperative compression (grade 1B). For the incompetent SSV, the recommendation is high ligation of the vein at the knee crease about 3 to 5 cm distal to the saphenopopliteal junction with selective stripping of the incompetent portion (grade 1B). In addition, the consensus was that endovenous thermal ablation (RFA and laser) was recommended over surgery for saphenous incompetence treatment based on reduced convalescence, pain, and morbidity (grade 1B) and over foam sclerotherapy due to improved efficacy (grade 1B). The elimination of saphenous reflux has also been found useful in treating the more advance stages of CVD (C₆), the venous ulcer. A commissioned SVS/AVF systemic review and meta-analysis of surgical interventions versus conservative therapy favored surgery over compression alone for ulcer healing with the quality of evidence low resulting in a suggestion favoring ablation over compression therapy alone to improve ulcer healing.^{270,276} While the same analysis demonstrated that surgery was statistically better than compression in preventing recurrence but some design and baseline imbalances in the two instrumental RCTs decreased the level of evidence resulting in a recommendation in favor of surgery of grade 1B. In addition, in patients with a healed ulcer, ablation in addition to standard compression therapy is recommended to prevent recurrence (grade 1C) and in patient with skin changes at risk of venous ulceration, the same treatment is suggested (grade 2C).

Perforator Vein Ablation. Although effective in eliminating perforating vein reflux, open³⁴⁴ or even endoscopic ligation³⁴⁵ has been replaced with percutaneous methods of ablation due to decreased morbidity associated with the less invasive procedures. A systematic review of pertinent guidelines and RCTs suggests that there is no benefit in treating patients with mild/moderate venous disease by the addition of perforation ablation (ligation) and, in fact, some perforator veins revert to normal function after superficial incompetence is corrected.³⁴⁶ The pertinent available data have resulted in an SVS/AVF guideline, which recommends that incompetent veins in patients with varicose veins should not be treated (grade 1B).¹²⁶ No matter the ablating energy delivered (radiofrequency, laser or chemical) during percutaneous perforator vein ablation, ultrasonographic access, operative monitoring, and confirmation of results are routine and the procedure can be accomplished under local anesthesia. The ablating device is inserted into the pathologic perforator and is serially pulled back during activation to burn the perforator for its length or the sclerosant injected into it with a similar result. Prevention of energy delivery to the deep system prevents unwanted thrombosis and is most often accomplished by positioning the ablation device (when used) or properly compressing the vein when using sclerotherapy at or just slightly below the fascia. Various sclerosing agents have been used with minimal risk of DVT, skin infection, and an immediate success of 90% to 98% and a 2-year maintenance of occlusion of nearly 80%.^{347–349} RFA demonstrates a greater than 90% early ablation rate with > 80% free of reflux at 1 year and 5 years.^{350–353} Laser energy of various wavelengths has been used for this procedure with reports of ~100% occlusions immediately and 85% to 90% occlusion rate in mid-term follow-up.^{351,354} The addition of perforator ablation to superficial vein incompetence ablation in patient with venous ulcers and pathologic perforator veins appears to improve healing rates and reduces recurrence.^{268,346,355,356} The available data have been interpreted by the SVS/AVF Guidelines Committee to allow four basic recommendations.²⁷⁶ In patients with active ulcers and both superficial and perforator incompetence to the pertinent ulcer bed, it is suggested that both are ablated to aid in ulcer healing and to prevent recurrence (grade 2C) but in patients without active ulcers the addition of perforation ablation can be simultaneous or staged on the basis of outcome (grade 2C). It is suggested that isolated “pathologic” perforators are ablated (grade 2C). It is recommended that “pathologic” perforation ablation be percutaneous rather than an open procedure to eliminate the need for incisions in areas of compromised skin (grade 1C).

Iliac Stenting and Venous Bypass. Endovascular stenting of iliac vein stenosis/obstruction involves percutaneous access of a nondiseased caudal vein (popliteal, femoral, common femoral vein) with guidewire/catheter access across the lesion under fluoroscopic guidance and generally intravascular ultrasonographic confirmation of stenosis >50%. If confirmed, dilation with 12- to 18-mm diameter percutaneous balloons, depending on the iliac to common femoral vein involved, with subsequent self-expanding stent deployment to maintain the dilation. This is accomplished from normal outflow (generally IVC) to distal normal vein even to less trochanter location within the common femoral vein if

needed to ensure good inflow. Extension to below the inguinal ligament is acceptable in the treatment of venous occlusive disease.³⁵⁷ Eliminating significant outflow obstruction in symptomatic patients has decreased edema, pain symptoms, and improved QOL parameters.^{127,152,197,358–360} It will often result in venous ulcers healing, many of which have associated untreated lower leg venous insufficiency, at an initial rate of 68% with only 8 of 101 healed ulcers recurring within 5 years, whether preformed for primary or postthrombotic occlusion.³⁶⁰ Parameters of venous reflux are not worsened following resolution of the occlusive iliac vein occlusive disease.³⁶⁰ The primary and assisted primary stent patency rates at 3 years is 75% and 92% and at 6 years 69% and 89%, respectively (Fig. 98-2).^{360,361} Many studies in multiple centers now confirm these earlier results with a cumulative patency rate of 90% and ulcer healing rates of 60% to 80%.^{362–367} This intervention has been performed for significant clinical symptoms (C₃ or C₂ with pain) and based solely on a greater than 50% morphologic stenosis found on transfemoral venography or intravascular ultrasonography.^{152,360,361} Potential complications include DVT, access site complications, retroperitoneal hematoma, and other catheter- and balloon-related problems with essentially no mortality associated with the procedure.^{225,360,361,368} When technically feasible, endovascular intervention has replaced more invasive approaches. As a result of accumulating data, the SVS/AVF Guidelines Committee has recommended venous angioplasty and stent recanalization in addition to standard compression therapy to aid in venous ulcer healing and prevention of ulcer recurrence in patients with proximal venous occlusion/severe stenosis and C_{4b}, C₅, and C₆ disease (grade 1C).

Figure 98-2. Life-table presentation demonstrates the patency rates of iliac venous stents placed for symptomatic occlusive venous disease. (After Neglén P, Hollis KC, Olivier J, Raju S. Stenting of the venous outflow in chronic venous disease: long-term stent-related outcome, clinical and hemodynamic results. *J Vasc Surg* 2007; 46:979–990.)

The open surgical procedures used to relieve proximal IVC or iliac vein occlusions utilize the native saphenous vein or polytetrafluoroethylene (PTFE) graft material as the conduit to bypass from a nondiseased distal vein to a disease-free proximal or collateral axial vein. Vena cava or bilateral iliac veins occlusion reconstructions often use PTFE grafts to allow a proper size match.^{369,370} If a single iliac vein is severely stenosed or occluded and percutaneous methods have failure, cross-femoral venous bypass or direct repair of the iliac vein can be performed.^{217,371} Patient survival should be considered prior to aggressive intervention if iliac vein compression is due to a cancerous encroachment. The cross-femoral venous bypass (Palma procedure) is performed by passing a vein graft or graft material via a suprapubic subcutaneous tunnel to the contralateral femoral vein. The saphenous vein or prosthetic graft is then connected to the unaffected femoral vein by an end-to-side technique after anastomosis on the affected side. The key to success of this surgery may be graft diameter. If the native vein is less than 4.5 mm in diameter, better success may be achieved with a 10-mm diameter PTFE graft, although others would question whether PTFE is superior to vein in this location.^{369,372} An arteriovenous fistula is generally used to increase flow through the graft in the immediate postoperative period. This fistula can then be ligated in 1 to 3 months or left open long term if no unwanted sequelae are noted. In one series, venous reconstruction for ileofemoral and IVC obstruction reported a 62% 3-year patency with the Palma procedure demonstrating the overall best patency (83% 4-year).³⁶⁹ Mortality was minimal and wound complications rare. Based on the limited current available data, the guideline for treating

bilateral proximal venous occlusion/stenosis in patients with recalcitrant venous ulceration and no endovascular option is a suggested open intervention using externally supported PTFE graft in addition to standard compression therapy (grade 2C).¹⁹³ In the same scenario, but with unilateral iliofemoral venous disease, the suggested therapy is an open surgical bypass using saphenous vein if available and sufficiently large with the alternative being a synthetic graft (grade 2C). When inflow is an issue during open operation, a distal adjunctive arteriovenous fistula (4 to 6 mm in diameter) is suggested (grade 2C).

Indications for a saphenopopliteal vein bypass are symptomatic patients with isolated femoral or popliteal vein occlusion, a patent common femoral and ilio caval system, a nonvaricosed saphenous vein, and femoral phlebitis inactive for at least 1 year. In addition, conservative therapy must have failed, and venous hypertension must be documented. These distal to proximal venous bypasses use autogenous vein as the conduit of choice and bypasses extend from distal to proximal nondiseased segments.³⁷² This operation is rarely performed.

Although not yet proven as a method of treating occlusive venous disease due to prior thrombosis, some data suggest that endophlebectomy (operative removal of synechiae and septa) of iliac, femoral, popliteal, and even tibial veins is possible and can result in a 77% primary patency rate at 8 months.³⁷³

Venous Valve Repair or Replacement

The goal of venous valve repair or replacement is the prevention of deep venous reflux and, therefore, a decrease in prolonged distal venous hypertension. These interventions are considered only after all other more easily treated venous pathology has been addressed by the surgeon in charge. During the conduct of these operations, several observations influence what the surgeon can offer a given patient. If operative handling of the suspect valve results in vasoconstriction and secondary incompetence (often determined by a standard “strip test”), an external valvuloplasty or a prosthetic sleeve technique may be viable options.³⁷⁴ For a valve station requiring an in situ repair, careful adventitial dissection of the valve attachment lines facilitates proper venotomy when required and helps to verify the feasibility of valve repair.¹⁸⁰ A lack of valve attachment lines may signify the destruction of the valve as a postthrombotic sequela, prompting something other than an in situ repair.¹⁸⁰ Valvuloplasty of any sort is most commonly performed in the femoral or popliteal location due to size and hemodynamic considerations.

Figure 98-3. Open valvuloplasty to repair an insufficient valve can be accomplished by various venotomy incisions. **A:** The method of Kistner. **B:** The method of Raju. **C:** The method of Sottirai. **D:** The method of Tripathi and his colleagues.

An internal valvuloplasty or an open direct valve repair has been the mainstay for the repair of primary venous valvular reflux for decades. This technique involves venotomy and suturing of the elongated valve leaflets under direct visualization with fine polypropylene suture (7 or 6 to 0) to

tighten the valve cusps. Kistner and colleagues¹⁵⁴ reported success with a longitudinal venotomy extending through the valve commissure in 1968 (Fig. 98-3). Raju³⁷⁵ championed a supracommissural approach involving a transverse venotomy at least 2.5 cm above the valve. Sottiurai³⁷⁶ devised a hybrid approach (a “T”-shaped venotomy), using a supra-avalvular transverse venotomy with distal extension into the valve sinus. A “trapdoor” approach involving two transverse incisions (supra-avalvular and infra-avalvular) connected by a single vertical incision through the commissure has been described by Tripathi and Ktenidis (see Fig. 98-3).³⁷⁷ Plication of approximately 20% of the valve leaflet length tends to restore valve competency in the majority of cases.³⁷⁸

The technique of external valvuloplasty offers the advantage of valve repair without venotomy.³⁷⁹ It is performed by placing sutures transmurally through the valve attachment lines and, when tied, reduces the commissural angle and vein diameter, resulting in a competent valve. The valve leaflets are generally not captured or reefed by this method. Reported results suggest that it may be less durable than the more precise open valvuloplasty, but patient selection plays a key role.³⁷⁹ A modification (limited anterior plication) involves only anterior vein dissection and then reefing of the cusps using a running mattress suture.³⁸⁰ It has been described in conjunction with saphenous vein stripping and limited to the femoral vein valve. Another modification of this technique features the use of an angioscope.³⁸¹ A side branch of the GSV allows introduction of an angioscope, which is advanced into the femoral vein to a position above the incompetent valve and external sutures are then placed under direct vision.³⁸¹ Following a learning curve while using the angioscope, Raju et al.³⁸² demonstrated good clinical and competency data with the “transcommissural” technique without the use of the angioscope with 30 months of follow-up. In these last two methods, the venous valve cusps are actually engaged with the suture and, therefore, the cusps are tightened directly much like the open method of repair.

External banding has been employed when dissection vasospasm renders a valve spontaneously competent. The technique uses an external sleeve made of synthetic material wrapped circumferentially around the vein at the site of the valve and tightened to diminish the size of the vein lumen until the valve is competent. The sleeve is then anchored in place to the adventitia by sutures to avoid slippage. It has achieved good results when used in select patients.^{229,383,384} One group of investigators has been more aggressive with this approach, utilizing the technique in patients with more severe valvular reflux and often placing multiple external cuffs.³⁸³

Venous valve transplantation is an option when the valve is absent or destroyed. This procedure was first reported clinically by Taheri³⁸⁵ in 1982. A 2- to 3-cm segment of upper extremity vein containing a competent valve (or a reparable one) is first removed. The incompetent femoral vein is opened below the takeoff of the profunda femoris vein, and the axillary vein segment is sutured into place following the removal of an appropriate length of femoral vein. The popliteal location may be more appropriate if the femoral location does not control all axial reflux into the leg, for example, if the profunda femoral vein system is also incompetent. The proximal anastomosis may be accomplished first to confirm the competence of the newly transplanted valve and to allow distention and lengthening of the vein/valve to facilitate the distal anastomosis. For vein transplantation in trabeculated postthrombotic veins, investigators³⁸⁶ have excised intraluminal synechiae to create one acceptable lumen for transplantation. Interrupted sutures are preferred to avoid suture line stenosis.³⁷⁸ Valve competence is determined by the intraoperative strip test. An external sleeve can then be placed to prevent late dilatation of the repaired segment and because approximately 40% of axillary vein valves are incompetent at explant, a bench repair may be required to restore competency.^{180,378,387}

A less common option for the PTS is valve transposition. If a venous valve is competent in one of the major thigh venous systems, then a transposition procedure can be performed placing the incompetent venous system below the competent valve. Most commonly, the femoral system is incompetent and the profunda femoris valve remains competent. Here, the incompetent femoral vein can be transected and reimplanted distal to the competent valve in the profunda femoris vein. Alternatively, the incompetent femoral system can be placed below a competent valve in the GSV or when the profunda femoris venous system is incompetent, it may be placed distal to a competent valve in either the femoral vein or the GSV. A technique has been described for transposition of the ipsilateral valve-competent GSV to the femoral vein and subsequent ligation of the femoral vein proximally, yet distal to the takeoff of the profunda femoris vein to escape problems with diameter mismatch.³⁸⁸ At 10 years, 55% of the patients were reported to be ulcer-free.

Aggressive venous valve surgery requires appropriate consideration of perioperative adjunctive care: prophylactic antibiotics, intraoperative heparin use especially if the vein is opened, the use of pneumatic

compression devices postoperatively, and the use of LMWH or IV heparin in the postoperative period. Some use closed suction drainage of wounds to avoid hematoma and seroma formation. Warfarin should have an initial target INR range of 2.0 to 2.5 for the first 6 weeks and some would advocate a subsequent decrease to 1.7 to 2.0 until 4 months when it is discontinued. Adjustments are made to accommodate those with an increased risk of thrombosis. One suggested that long-term regimen is “minidose” warfarin, which utilizes daily doses of 1 to 2.5 mg to prevent thrombosis.^{180,389} Although many surgeons encourage the use of compressive support, patients often do not comply but still have acceptable clinical results.^{182,183}

Valve repair procedures are well tolerated by most patients and have a low morbidity, as well as essentially zero mortality in most series.¹⁵⁴ Hematoma and seroma formation are noted in less than 15% of cases, depending on the level of anticoagulation used.^{182,378,390–392} DVT occurs in less than 10% of cases in most series and even if higher is not associated with clinical sequelae, while the pulmonary emboli risk is well less than 1%.^{180–182,378,390–392} Wound infections have been seen in 2% to 7% of cases.^{180,182,378,392}

Kistner et al. reported long-term follow-up of internal valvuloplasty spans over decades and is reported in life-table format (Fig. 98-4). Valve competency is 60% to 70% at 5 years in most series.^{181–183,229,375,377,393–398} In general, a patent and competent valve translates into clinical improvement and a healed ulcer, while the reverse is true with recurrent reflux. This is true for all types of single station venous valvular reconstructions.

External valvuloplasty without direct cusp repair (isolated wall diameter reduction) appears to perform less well in all aspects than open valvuloplasty.^{229,392} However, the “transcommissural” technique that does directly repair the slack valve cusps performs much like open valvuloplasty with a competency rate of more than 60% at 3 years and >70% ulcer free rate up to 5 years.³⁸² External banding performs adequately in select cases or as adjunctive procedures during other venous valve surgery.^{229,383,384}

Valve transposition demonstrates clinical improvement in 50% to 60% of patients after 3 to 5 years of follow-up.^{154,181,182,388–391,393–397} The valve competency rate varies from 30% to 80% and is reflected in the clinical improvement noted.^{154,181,182,388–391,393–397}

Figure 98-4. Life-table demonstrates the cumulative clinical success rate based on type of valve reconstruction procedure. The valve repair operation is valvuloplasty as performed by Kistner and associates via the Kistner technique. “Other operations” refer to valve transpositions ($n = 14$), superficial femoral vein valve transplantations ($n = 2$), and combined valve repair and transposition procedures ($n = 3$). Numbers in parentheses indicate the number of valve repairs remaining in the study at that time point. Significant difference exists between valve repair and other operations. (After Masuda EM, Kistner RL. Long-term results of venous valve reconstruction: a four to twenty-one year follow-up. *J Vasc Surg* 1994;19:391.)

Valve transplantation is undertaken in the most complex and difficult conditions. Clinical improvement is seen in about 50% of patients even at 8 years of follow-up, and it remains a good option in cases where other techniques are not possible.^{153,154,379} There does not appear to be a difference between reported competency rates or clinical results when considering the location of valve repair (femoral vs. popliteal), but overall the competency rates reported are inferior to internal valvuloplasty.^{376,385,397,399–404} There are data to support that contention that repairing multiple valves in the same axial system translates into longer clinical benefit, but this approach does, of course, add risks at the initial operative intervention.^{382,383,392,405}

In general, patients with postthrombotic reflux tend to have more problems maintaining healed ulcers than those with a primary etiology of reflux, as noted from the results of internal valvuloplasty (generally a primary etiology) versus those requiring transplantation or a transposition operative

approach.¹⁸² Review of pertinent data has resulted in guidelines to reference when treating patients with C_{4b}, C₅, and C₆ disease.²⁷⁶ It is suggested that in such patients with structurally preserved deep venous valves, individual valve repair can be offered (grade 2C). If no structurally intact exists, then valve transposition or transplantation is suggested treatment (grade 2C).

Valve Substitutes

Autogenous tissues appear to be the only material that currently can act as a substitute valve with some hope of success in the clinical arena. Using donor vein, after trimming adventitia and part of the media, to fashion semilunar cusps within the deficient recipient vein, Raju and Hardy¹⁸⁰ have reported acceptable clinical results. Another approach invaginates a stump of the long saphenous vein into the femoral vein to fashion a bicuspid valve, 19 of 20 reconstructions were patent and competent at a mean of 10 months with one valve demonstrating reflux.⁴⁰⁶ No other series have reproduced these findings to date. The newest innovation has been to use an ophthalmic knife or other fine tool to dissect the intima/media wall of the thickened postthrombotic vein wall into one or two sheets and thereby fashion the valve cusp(s).⁴⁰⁷ This technique has been reproduced by another investigator.⁴⁰⁸ A recent improvement has been to place two sutures on the cusp(s) to hold the valve in the semiopen position and thereby to prevent valve collapse and improve neo valve competence. The results with this modification include 21 operations (mean follow-up 11 months) with all valves competent, a 95% ulcer healing rate and two recurrences (9.5%).⁴⁰⁹ In this highly select group of patients, the SVS/AVF Guidelines Committee suggests consideration of autogenous valve substitutes in addition to standard compression therapy to aid in venous ulcer healing and recurrence prevention (grade 2C).²⁷⁶

Venous Ulcer Wound Care

The quest to heal venous ulcers has generated a myriad of potential topical agents to aid in ulcer healing. Topical antibiotics and dressings containing antimicrobials may retard wound healing and cause allergic reactions and are not recommended for the treatment of venous ulcers.^{276,410} Growth factors and cytokines in addition to compression when provided as isolated topically applied agents have not demonstrated efficacy when compared to placebo. Review of the literature demonstrates inconsistent results or studies with insufficient data to determine with any certainty the efficacy of such adjuvants.^{411,412} A number of topical dressings applied on the ulcer bed and beneath the compression dressing have been investigated to determine if ulcer healing could be improved. Hydrocolloids (e.g., DuoDerm), foams (e.g., Allevyn), alginates (e.g., Sorbsan), hydrogels (e.g., Intrasite Gel, or Debrican), and others (e.g., Opsite) have been studied. Insufficient data is available to make firm conclusions, but it is clear that the nature and amount of the exudates present may provide a rationale for the benefit of one or the other of these dressings in a given patient.^{413–415} The SVS/AVF 33.Guidelines Committee suggests that the wound dressing be selected, which absorbs wound exudates and protects the periulcer skin from damage (grade 2B).²⁷⁶

Surgical debridement to healthy tissue, when required, benefits the rate of ulcer healing and does not lead to a higher risk of systemic infection.^{410,416–418} It is especially beneficial when evaluated as adjuvant care to the standard methods of venous ulcer wound care.^{414,419} The use of local anesthetic during debridement of venous leg ulcers has been found statistically beneficial in lowering pain scores in a Cochrane analysis of six trials.⁴²⁰ This and other pertinent data are the basis of recent guidelines for optimal patient care.²⁷⁶ Surgical debridement is recommended to remove slough, nonviable tissue and eschar (grade 1B) using local anesthesia to minimize discomfort (grade 1B).

Hydrosurgical, enzymatic, and larval therapy are effective methods of venous ulcer debridement, but none have been found more effective than surgical debridement and can be more expensive. Current guidelines suggest each as a potential alternative to surgical debridement when a trained practitioner is not available to provide surgical debridement (grade 2B/C).²⁷⁶

For resistant venous ulcers, defined as those that fail to demonstrate improvement in a minimum of 4 to 6 weeks of standard wound therapy, adjuvant wound therapy options should be considered.^{276,421} These ulcers can be extensive, and skin grafting allows for coverage of raw surfaces to speed the healing process. Once the ulcer has a clean base of granulation tissue, a split-thickness skin graft can be applied. There are reports on improved healing with skin grafting for chronic venous ulceration.⁴²² Skin grafting is generally considered only when ulcer healing has not occurred following diligent conservative management.⁴²³ An alternative or precursor to an autologous skin graft may be one of a variety of skin substitutes. A number of skin substitutes have been used to aid in venous ulcer healing (e.g., fresh allografts, porcine dermis) but for most there are insufficient data available to determine whether

venous ulcer healing is improved.⁴²⁴ However, the biologically active bilayered human skin equivalent with an allogenic epidermal and dermal layer has demonstrated more promise and statistically improved the time to complete healing.^{414,424,425} Porcine small intestine submucosa (SIS) is primarily a collagen-based extracellular matrix with retained biologically active components. In a study of SIS and when adjusted for ulcer size, SIS was three times as likely to heal as the control group ($P = 0.007$) and at 6 months there was no recurrence in the SIS group.⁴¹⁹ This manuscript was included in a review of the literature as an RCT demonstrating significance when used to heal venous ulcers.⁴¹⁴ The use of these skin substitutes is suggested as guideline adjuvant therapy in recalcitrant venous ulcer care (grade 2 A/B).²⁷⁶

The Pelvic Congestion Syndrome

This distressing clinical condition can result from gonadal vein and/or hypogastric vein reflux. Pelvic pain is a constant complaint and can be disabling. Gonadal vein reflux may be best managed with gonadal vein excision due to its many areas of potential reflux, but an endovascular approach using coils, sclerosants, or a combination can also be successful and is the most common approach currently.⁴²⁶ Hypogastric vein reflux may be best managed by percutaneous embolization.⁴²⁷ When the elimination of proximal reflux does not resolve superficial varicosities, the management involves techniques used for saphenous vein branch varicosities.

SECTION N: PEDIATRIC SURGERY

Chapter 99

Fetal, Neonatal, and Pediatric Physiology

Samir K. Gadepalli and George B. Mychaliska

Key Points

- 1 Certain aspects of fetal and neonatal physiology differ markedly from adult physiology, whereas the physiology of older children and adolescents approximates adult physiology.
 - 2 During fetal life, the right ventricle provides about 65% of the fetal cardiac output and the left ventricle ejecting the remaining 35%.
 - 3 Prematurity and critical illness are both associated with persistent fetal circulation. Under these conditions, the RV continues to contribute a large portion of the cardiac output and the postductal saturations will be significantly lower than the preductal saturations.
 - 4 Surfactant is a mixture of phospholipids, neutral lipids, and specific proteins that, by virtue of their amphipathic nature, decrease surface tension, stabilize small alveoli, and improve overall alveolar inflation.
 - 5 The neonatal heart increases its cardiac output primarily through increases in heart rate.
 - 6 The primary cause of neonatal bradycardia is hypoxia.
 - 7 Ventricular septal defect (VSD) is the most common heart defect occurring in nearly a third of neonates with congenital heart disease.
 - 8 Patent ductus arteriosus: fluid restriction is the first line of therapy when appropriate with indomethacin reserved for persistent cases to help stimulate closure.
 - 9 An infant enduring water deprivation can only increase urine osmolality to 600 mOsm/kg, whereas adults can concentrate to 1,200 mOsm/kg.
 - 10 A term newborn grows at 25 to 30 g/d over the first 6 months, doubling their birth weight by 5 months, tripling it by 12 months.
 - 11 The enteral nutrition of choice in neonates is breast milk even in the premature or very low-birth-weight (<1,500 g) infant.
-

INTRODUCTION

An understanding of fetal, neonatal, and pediatric physiology is critical to understanding the pathophysiology and treatment of fetal and pediatric surgical problems. As distinct from adult physiology, fetal, neonatal, and pediatric physiology must account for varying degrees of growth and maturation and for major physiologic transitions particularly from the prenatal to the postnatal period. New insights into fetal and neonatal physiology coupled with technologic advances have led to pioneering treatment approaches for congenital anomalies and the treatment of extreme prematurity.

1 First, although the old pediatric surgical adage “children are not small adults” still holds true, the physiology of older children begins to approximate the physiology of adults. As such, this chapter focuses primarily on the unique and distinguishing physiology of the fetus and neonate. Since prematurity remains an unsolved problem, a section is also devoted to this cohort of neonates.

Second, the topic of physiology is broad and it was impossible to cover each organ system in depth. We focused on critical topics that are necessary to the practice of pediatric surgery and touched on areas that are innovative and promising.

Third, where applicable, we intended to also make this resource practical to the practice of pediatric surgery. Where applicable, we discuss specific pediatric surgical diseases to illustrate physiologic principles. Similarly, some aspects of medical management as it relates to unique physiology are discussed.

Finally, we acknowledge that our understanding of fetal, neonatal, and pediatric physiology is not static and remains an exciting area of scientific inquiry. As our knowledge grows, we can not only

better understand pathophysiology of pediatric diseases, but also develop effective medical and surgical treatments.

Fetal Physiology

Fetal Morphogenesis

The human embryo begins as a single cell. During gestation, a fertilized egg divides and differentiates into more than 200 different morphologically recognizable cell types. Development begins with the fusion of the male and female gametes at fertilization. The earliest form of an embryo is called a zygote. Initially, the diploid chromosome number is restored by fusion of the two haploid gametes from each parent.

The zygote undergoes a series of mitotic divisions and by the 8- and 16-cell stage, the embryo is called a blastocyst and consists of a clump of cells termed the inner cell mass, that are surrounded by a layer of trophoblast cells. Subsequent differentiation of the trophoblast results in a double-layered membrane which is a progenitor tissue of the chorion, the fetal portion of the placenta. Once the zona pellucida is shed, the blastocyst attaches and implants within the uterine endometrium. At the beginning of the third week of development, gastrulation ensues and is characterized by morphogenetic movements resulting in a primitive streak. Some epiblast cells enter the streak, while others remain within the epiblast to become the embryonic ectoderm. At the primitive streak, sets of polarized epithelial cells within the epiblast transform into nonpolarized free cells termed mesenchyme, the second embryonic tissue. These events are mediated by adhesive molecules located on the cell surface as well as expression of homeobox genes and other signaling molecules leading to patterning of axial and nonaxial structures. The primitive streak provides a means by which subsets of epiblast cells can ingress and be distributed to more ventral regions of the embryo as the endoderm and the mesoderm. The first cells through the streak comes the endoderm followed by cells that form the notochord which defines the axis of the embryo and plays a significant role in the nervous system. Due to cleavage and gassed relation, population of cells in various stages of the termination, are brought together in new spatial relationships, which permits new tissue interactions. Subsequent organogenesis results from these tissue interactions. These interactions are mediated by a variety of signaling molecules such as growth factors, secreted factors, and transcriptions factors, produced by cells and often concentrated in the extracellular matrix. The embryology and physiology of select organ systems will now be described.

Lung Development

The respiratory system consists of elements of air conduction and exchange. The uptake of oxygen from the environment and removal of carbon dioxide serves to maintain cellular aerobic metabolism and acid–base balance. In order to effectively perform these processes, normal structural and cellular development is essential. The respiratory system must develop through five phases: embryonic, pseudoglandular, canalicular, saccular, and alveolar. The boundaries between these phases merge into each other with overlap at any given time point between areas of the lung and vary temporally between individuals.¹

Embryonic Phase (3 to 7 Weeks). Lung growth begins around postconception (p.c.) day 25 or 26 with the outgrowth of a small diverticulum from the ventral wall of the foregut called the primitive respiratory diverticulum or lung bud. This extends in the ventral caudal direction into the surrounding mesoderm, growing anterior and parallel to the primitive esophagus. Within a few days, the groove between the diverticulum and the foregut closes with the only luminal attachment remaining at the site of the future hypopharynx and larynx.² By p.c. day 28, the respiratory diverticulum bifurcates into the right and left primary bronchial buds. This is followed by a second round of branching occurring around the fifth week p.c. yielding the secondary bronchial buds. Finally, the third branching takes place during the sixth week p.c. producing 10 tertiary bronchi on the right and 8 on the left. The vascular components of the respiratory system also begin to develop with the pulmonary arteries forming as branches off the sixth aortic arch and the pulmonary veins emerging from the developing heart.

The primitive lung bud is lined by epithelium derived from endoderm which will become the epithelium lining the airways and alveoli. The lung buds grow into the surrounding mesodermal cells which will differentiate into the blood vessels, smooth muscle, cartilage, and other connective tissue. Ectoderm will eventually give rise to the innervation of the lung.¹

Pseudoglandular Phase (5 to 17 Weeks). The lung begins to take on a glandular appearance during

this stage of development. The lung is composed of multiple epithelial tubules surrounded by extensive regions of mesenchyme, giving a glandular appearance. Cellular proliferation rate increases during this stage and by p.c. week 16, all bronchial divisions are completed with further growth occurring only by elongation and widening of existing airways. The intrapulmonary arterial system develops branching in parallel with the bronchial and bronchiolar tubules. The respiratory epithelium begins to differentiate with cilia appearing in the proximal airways and cartilage begins to develop to support the airways.¹ Concurrently, closure of the pleuroperitoneal folds is completed.

Canalicular Stage (16 to 26 Weeks). This stage is named due to the appearance of vascular canals or capillaries and the increase in the interstitial compartments forming the air–blood barrier. The capillary beds rapidly expand with condensation and thinning of the mesenchyme, starting the first critical step in the formation of the gas exchange regions of the lung. The ingrowth of capillaries results in thinning in one population of overlying epithelial cells, narrowing the air–blood interface and differentiating into type I pneumocytes. In other overlying epithelial cells, lamellar bodies associated with surfactant synthesis appear, identifying type II pneumocytes. The airways continue to develop with completion of the airways through the level of the terminal bronchioles with their associated acinus. Branching of the distal airspaces continues until there are a total of 23 subdivisions.

Saccular Stage (24 to 38 weeks). During this stage, the terminal clusters of acinar tubules and buds dilate and expand into transitory alveolar saccules and ducts with a marked reduction of the surrounding mesenchymal tissue. By 24 weeks, there is a sufficiently thin alveolar-capillary membrane distance to participate in gas exchange (0.6 μm) with the efficacy of exchange being determined beyond this point by the total surface area available for exchange. By the end of this stage, three additional generations of alveolar ducts have formed and the conducting airways have developed mucous and ciliated cells. Overall, cell proliferation slows and ultrastructural cytodifferentiation occurs. The saccules consist of smooth-walled airspaces and a thick interstitial space. Type II epithelial cells continue to mature and there is an increase in surfactant synthesis, but overall levels remain low.

Alveolar Stage (36 Weeks to 2 Years). This is the final stage of lung development and is characterized by the formation of secondary alveolar septa which divide the terminal ducts and saccules into true alveolar ducts and alveoli. There is maturation of the alveolar-capillary membrane, which increases the surface area for gas exchange. As the terminal saccule restructures during this stage, the double capillary network fuse becoming a single capillary network with each capillary being simultaneously exposed to at least two alveoli. The barrier to gas exchange thins to a few nanometers. Type I and type II cells increase in number, but only type II cells are proliferating actively suggesting that type I cells are derived from type II cells.

Physiologic Control of Fetal Lung Growth

While the fetus and neonate proceed through the phases of lung growth and development, physical factors play an important role in directing and assisting in this process. While not all factors affecting this process are well understood, the role of fetal lung fluid (FLF) and mechanical distension appear to play critical roles. During fetal life, the lung produces a unique fluid, FLF that is a result of net transepithelial chloride and sodium flux and is produced within the lungs and leaves via the trachea.³ As the fluid moves from the lung toward the oropharynx, it is either swallowed or enters the surrounding amniotic fluid. Throughout gestation, the volume of FLF increases with studies in ovine animals demonstrating FLF volume of 35 to 45 mL/kg which is significantly higher than functional residual capacity (FRC) postbirth (25 to 30 mL/kg).⁴ This keeps the airway distended in order to stimulate growth.

The volume of FLF is primarily regulated by the resistance to lung liquid efflux through the upper airways and by fetal breathing movements (FBM) which include the associated diaphragmatic activity and the volume is largely independent of production. When there is no FBM (apnea), the transpulmonary pressure is usually 1 to 2 mm Hg above the amniotic sac pressure due to the elastic recoil of the chest wall. Lung fluid efflux is prevented by high resistance of the upper airways which prevent FLF loss and maintains an approximately 2 mm Hg distending pressure and fetal lung expansion.⁵ During periods of FBM, the larynx actively dilates to decrease the resistance to FLF efflux allowing fluid to leave at an increased rate. To compensate during periods of FBM, rhythmic contraction of the diaphragm slows the loss of lung fluid and helps to maintain lung expansion during periods of low upper airway resistance demonstrating that FBM serve to maintain lung expansion and promote

lung growth. Sustained reduction of fetal lung expansion can slow the structural development of both the vascular bed and alveolar epithelial cell phenotypes. On the other hand, prolonged overexpansion of the fetal lungs via tracheal occlusion is a potent stimulator for fetal lung growth and tissue remodeling.⁶

Additionally, it has been observed that fetal airways undergo peristaltic contractions similar to the gut which move intraluminal contents distally and cause expansion of end buds which also likely play a role in fetal lung growth and expansion.⁷ Postnatal formation of significant numbers of alveoli continues to occur for the first 1.5 to 3 years after birth with the lung growth continuing for another 15 to 18 years when the chest wall stops growing.

Fetal Circulation and Placental Gas Exchange

The umbilicoplacental circulation is critical for normal growth and development of the fetus. The umbilical artery and vein are long and muscular and the placental vascular bed is high flow and low resistance. Although the umbilical vessels are highly vasoactive, they remain nearly maximally dilated during pregnancy. The umbilical arteries arise from the internal iliac arteries and curve along either side of the bladder before entering the umbilical cord where they form a loose spiral around a single umbilical vein. The umbilical arteries branch at the fetal surface of the placenta to form many radially oriented chorionic arteries located on the surface of the chorionic plate. Veins within the villi merge progressively to return blood from the placenta to the chorionic veins on the fetoplacental surface entering a single umbilical vein. Venous blood is then returned to the fetal inferior vena cava through the parallel arrangement of the ductus venosus and the hepatic vessels. The ductus venosus plays a critical role in fetal circulation because it shunts highly oxygenated and nutrient-rich umbilical venous blood to the brain and myocardium instead of the fetal liver. The percentage of umbilical blood flow bypassing the hepatic circulation through the ductus venosus decreases from approximately 40% at midgestation to 20% at term.⁸

The fetal circulation with intra- and extracardiac shunts permits the lungs to be bypassed and results in the delivery of more highly oxygenated blood flow to the brain and heart. Due to the shunts, fetal organs receive blood from both ventricles which forms a parallel circulation. The ductus venosus, foramen ovale, and ductus arteriosus (DA) are the shunts required for fetal circulation. The first shunt encountered is the ductus venosus, which shunts half of the blood away from the liver directly to the heart. Highly oxygenated blood from the ductus venosus mixes with blood from the inferior vena cava, but preferential streaming directs blood with more oxygen across the foramen ovale into the left atrium. As a result, highly oxygenated blood travels to the left ventricle and is ejected into the aorta, thus feeding the coronary arteries and arteries to the brain. In contrast, the mostly deoxygenated blood from the superior vena cava (SVC) tends to stream directly into and across the tricuspid valve into the right ventricle, where it is then ejected out the pulmonary artery. Due to the high pulmonary vascular resistance, the blood is shunted via the DA, entering the proximal descending aorta just past the left subclavian artery at the end of the aortic arch. The shunted blood entering the descending aorta perfuses the lower body and returns to the placenta via the umbilical arteries. Only 10% of the combined cardiac output (CO) perfuses the lungs ([Fig. 99-1](#)).

2 Fetal CO is described as combined ventricular output or combined CO. The right ventricle ejects against high-resistance lungs and lower body and low-resistance DA and placenta. The left ventricle ejects against high-resistance brain, upper body, and aortic isthmus. Given a lower afterload, the right ventricle provides about 65% of the fetal CO and the left ventricle ejecting the remaining 35%.

Umbilical blood flow gradually increases as the fetus grows. The umbilical blood flow during the third trimester remains fairly constant at 110 to 125 mL/min/kg of fetal weight.^{9,10} Fetal biventricular CO is approximately 450 mL/min/kg and remains fairly constant. Thus, umbilical blood flow represents approximately 30% of fetal biventricular CO. The integrity of the placental circulation is essential to fetal growth and development. Total uterine blood flow increases substantially during pregnancy, but umbilicoplacental blood flow remains approximately 200 mL/min/kg of fetal weight throughout gestation. Blood flow is mediated by a number of factors including ANG II, catecholamines, arginine vasopressin (AVP), nitric oxide (NO), prostaglandins, estrogen, and progesterone. The placenta has many physiologic functions. Placental transfer, not just flow, is involved in determining fetal growth. Idiopathic intrauterine growth restriction (IUGR) has been attributed to placental insufficiency due to oxygen delivery, flow, and transfer of nutrients particularly amino acid transporters. In IUGR, fetuses fail to achieve their full growth potential due to infection, drug abuse, maternal malnutrition, and placental insufficiency. Umbilical blood flow is lower in growth-restricted fetuses.¹¹

Fetal Cardiac Function and Oxygen Delivery

The fetus has immature structure, function, and innervation of the heart. The fetal heart is less compliant and thus shows a reduced ability to augment CO with changes in preload. The negative increased afterload on CO is exaggerated in the fetal heart. The Frank–Starling mechanism seems to remain the major regulator of CO in the fetus.

While fetal oxygen transport system is set up to provide optimal oxygen delivery and has the capacity to adjust delivery to match demand in the setting of the intrauterine environment, this system can be stressed as it adjusts to life outside the womb. The delivery of oxygen to tissues depends on the pressure gradient between the blood and the mitochondria and varies with regional oxygen delivery, tissue oxygen consumption and hemoglobin–oxygen affinity.

Oxygen is transported through the blood stream either dissolved in aqueous solution or bound to hemoglobin. Arterial oxygen content can be calculated using the formula: arterial oxygen content = $(\text{Hgb} \times 1.36 \times \text{SaO}_2) + (0.0031 \times \text{PaO}_2)$ where Hgb is hemoglobin concentration in grams, SaO_2 is the arterial saturation of hemoglobin, and PaO_2 is the arterial partial pressure of oxygen. If hemoglobin is 100% saturated then 1g of hemoglobin can deliver 1.36 mL of oxygen. The actual amount of oxygen carried by hemoglobin is variable and is defined by the hemoglobin disassociation curve ([Fig. 99-2](#)).

Normally, hemoglobin is close to 100% saturated, however, the sigmoidal nature of the curve ensures that the hemoglobin saturation remains high even at low PaO_2 . The hemoglobin disassociation curve is not static and hemoglobin's affinity for oxygen can be influenced by a number of factors. Hemoglobin has an increased affinity for oxygen with a left shift of the oxygen disassociation curve in alkalosis, hypothermia, decreased 2,3 diphosphoglycerate (DPG) or fetal hemoglobin. Hemoglobin's affinity for oxygen decreases in the setting of acidosis, hyperthermia, or increased 2,3 DPG. This facilitates unloading of oxygen at lower flow to the peripheral tissues.

Fetal hemoglobin (HgbF) plays an important role in the transport and unloading of oxygen in the fetal and neonatal periods. Human hemoglobin consists of three basic chain structures which include the alpha chain, beta chain, and gamma chain which make hemoglobin A (HgbA) of $(\alpha_2\beta_2)$ and hemoglobin F (HgbF) $(\alpha_2\gamma_2)$. The beta and gamma chains differ from each other by a few amino acid residues. The fetal hemoglobin has a significantly higher affinity for oxygen which favors uptake of hemoglobin across the placenta. Near term there is a period of accelerated erythropoiesis during which HgbA synthesis predominates with a gradual orderly, and not completely understood, transition in synthesis from γ to β hemoglobin chains.¹²

Figure 99-1. Fetal circulation. (From Rosdahl CB, Kowalski MT, eds. *Textbook of Basic Nursing*. Philadelphia, PA: Wolters Kluwer Health; 2012.)

Transition to Postnatal Life

3 One of the most critical and fascinating periods in human physiology is the changes which occur, usually in a matter of minutes, which allows a human to transition from surviving in the uterine environment to the external environment. Around the time of birth, epithelial cells cease production of lung fluid and begin to actively absorb it back into the fetal circulation. This process is facilitated by active sodium transport which is stimulated by thyroid hormone, glucocorticoids, and epinephrine.¹ During the first breaths, pulmonary arterial pO_2 increase and pCO_2 decrease resulting in pulmonary vascular dilation, decreased pulmonary vascular resistance, and constriction of the DA. Although pulmonary vascular resistance decreases dramatically at birth, pulmonary artery pressure, pulmonary blood flow, and pulmonary vascular resistance decrease gradually over the first few weeks of life. The increased pulmonary blood flow results in an increase in left atrial pressure and as a result, the flap-like foramen ovale closes in response to higher left atrial pressures relative to right atrial pressure. The RV compliance gradually increases as well, and the resultant change in the differences in ventricular compliance allows the flap of the foramen ovale to gradually close over in the first few days to week of life, minimizing mixing, so that the outputs of the left and right ventricles become equivalent. The DA closes in the first 24 to 48 hours of life as a result of changes in direction of flow, contractile elements, an increase in pO_2 , a drop in PGE synthesized by the placenta, and other humoral factors. Removal of the placenta results in a decrease in circulating prostaglandin levels and increasing pO_2 levels are a stimulus for ductal closure. When the foramen ovale or DA does not close, they are referred as patent foramen ovale (PFO) and patent ductus arteriosus (PDA). Certain clinical conditions may contribute to the persistence of fetal circulation or to the reappearance of fetal shunts under stress. Prematurity and

critical illness are both associated with persistent fetal circulation. Under these conditions, the RV continues to contribute a large portion of the CO and the postductal saturations will be significantly lower than the preductal saturations. In premature infants, the transition may be much slower and the DA may not close despite the usual changes in systemic and pulmonary vascular resistance and the subsequent reversal of flow. Cessation of umbilical blood flow results in closure of the ductus venosus and increase in systemic vascular resistance. This increases the left-sided heart pressures and closes the foramen ovale. With these changes, the transition to postnatal circulation is complete and the process of postnatal pulmonary dependence is initiated.

Figure 99-2. The oxygen dissociation curve shows the percent saturation of Hgb at various partial pressure of oxygen and demonstrates the equilibrium between oxyhemoglobin and deoxyhemoglobin. The sigmoidal shape is a result of the cooperative binding between the four hemoglobin polypeptide chains. An important point is the P_{50} which is the partial pressure of oxygen at which erythrocytes are 50% saturated with oxygen. When oxygen partial pressure is high, such as in the lungs, hemoglobin binds oxygen with increased affinity. When the partial pressure of oxygen decreases such as in the peripheral tissues, oxygen is preferentially unloaded. Multiple factors including acid-base, temperature, and 2,3 DPG affect hemoglobins affinity for oxygen shifting the curve resulting in more or less unloading of oxygen at a given partial pressure.

In order for gas exchange to occur in the developing lung, there needs to be intimate contact between atmospheric oxygen and capillary blood flow. This requires adequate alveolar ventilation and pulmonary blood flow. The neonate has a number of physiologic mechanisms which allow for matching alveolar ventilation (V) and pulmonary perfusion (Q) to optimize gas exchange. To accomplish this, an adequate alveolar gas volume and FRC must be established shortly after birth and sustained. Once the FRC is established, this serves as an intrapulmonary pool of oxygen. However, newborns are at increased risk for hypoxemia due to lower than adult pO_2 with less intravascular reserve, FRC closer to airway closure, and high metabolic demand in infancy resulting in quicker depletion of oxygen stores.

At birth, the oxygen demand in the infant increases in most species by 100% to 150%. Consequently, fetal hemoglobin with its increased oxygen affinity which was adequate for a fetus does not provide enough oxygen diffusion and delivery in the neonate. Postnatally, the infant's affinity decreases rapidly and reaches normal adult values by 4 to 6 months which corresponds to the amount of time necessary for the replacement of fetal hemoglobin by adult hemoglobin.¹³ The amount of HgbF decreases from around 75% to approximately 2% during the first year of life. Until this occurs, other mechanisms help the neonate to cope with the ex utero environment. One of the most important is an increase in the concentration of 2,3 DPG during the first few days of life. At birth, its level is near an adult's level of 5.43 ± 1.04 and increases to 6.58 ± 1.00 . This increase has a small direct effect on fetal hemoglobin, but also lowers the intracellular pH and thus decreases hemoglobin's affinity for oxygen.¹⁴

Surfactant

4 While many factors play a critical role in allowing for a smooth transition, one of the most clinically relevant pieces is the role surfactant in neonatal pulmonary mechanics and gas exchange. In pulmonary physiology, an important concept is surface tension and its effects on the pressure drop across an interface separating two phases of matter which was defined in the early 1800s by Young and Laplace.¹⁵ The pressure drop necessary to maintain or inflate air sacs of a given size is proportional to its surface

tension and inversely proportional to its radius. The work of breathing is consequently directly proportional to the surface tension. During development, surfactant production increases as type II pneumocytes mature and alveoli increase in size. Surfactant is a mixture of phospholipids, neutral lipids, and specific proteins that, by virtue of their amphipathic nature, decrease surface tension, stabilize small alveoli, and improve overall alveolar inflation. Surfactant reduces the hydrostatic driving force for pulmonary edema and decreases work of breathing. When deficient, it can lead to severe respiratory failure. Exogenous administration has been proven effective in prophylactic or rescue treatment for respiratory distress syndrome (RDS) in premature infants with a 40% reduction in death and a 30% to 50% reduction in the odds of pulmonary air leaks.¹⁶ Additionally, vitamin A supplementation may reduce the risk of chronic lung disease (CLD) in extremely low-birth-weight infants and was recommended in infants under 1,000-g birth weight though further studies have failed to confirm the finding.^{17,18}

Fetal Interventions

Fetal surgery has emerged as an independent subspecialty at the intersection of pediatric surgery, maternal fetal medicine, and neonatology. It is a field that has arisen from clinical necessity. Pediatric surgeons, maternal fetal medicine specialists, and neonatologists became frustrated with the management of a number of congenital structural anomalies in which the baby died or suffered severe life-long disability despite all efforts at postnatal treatment. With the advent of prenatal ultrasound in the 1970s, many conditions were diagnosed before birth. Fetuses were followed and the prenatal natural history was elucidated. It became clear that a component of organ failure was acquired because of ongoing alterations in fetal development caused by the anomaly. Thus, it made sense that fetal interventions may be of benefit – to correct the pathophysiology to restore normal fetal development in the hope of improving survival and decreasing morbidity.

Criteria that must be met to consider fetal surgery include: (a) accurate diagnosis of the condition and any associated anomalies that may have an impact on outcome; (b) reliable prediction of which individual fetuses will die or suffer serious long-term morbidity without fetal intervention; and (c) demonstration of improved fetal outcome with minimal maternal risk.

Fetal imaging is a critical component of the decision making process in fetal surgery. Prenatal detection and serial ultrasonographic evaluation of these disorders have enhanced our understanding of their natural history and pathophysiology, and have significantly improved perinatal management. Fetal conditions that may benefit from in utero intervention by a pediatric surgeon include myelomeningocele, twin to twin transfusion syndrome, sacrococcygeal teratoma (SCT), congenital diaphragmatic hernia (CDH), and congenital lung lesions (CLLs).

Sacroccocygeal Teratoma

The evolution of high-output cardiac failure before the development of placentomegaly and hydrops in a fetus with SCT is the sole indication for fetal surgical intervention. Furthermore, SCT may lead to maternal mirror syndrome (Ballantine syndrome).¹⁹ Fetal echocardiography and Doppler ultrasound measurements are important in the diagnostic assessment and follow-up of fetuses with these conditions. Increased aortic velocity, increased combined CO, increased cardiac-to-thoracic ratio, a dilated inferior vena cava, or reversed end-diastolic umbilical blood flow appears to be sensitive early predictors of impending hydrops and fetal demise.^{20,21} For fetuses under 28 weeks estimated gestational age (EGA), open fetal surgery and resection is the treatment of choice.

Congenital Diaphragmatic Hernia

At present, the role of fetal intervention in the management of fetuses with CDH is not clear. The pathophysiology of CDH involves both pulmonary hypoplasia and pulmonary hypertension.

Although the cause of CDH remains unknown, the consequences to pulmonary development and function are well known. If the pleuroperitoneal canal has not closed when the midgut returns to the abdomen by weeks 9 to 10, the abdominal viscera herniates into the chest cavity. This affects both ipsilateral and contralateral lung development, with hypoplasia more severe on the ipsilateral side. The herniation occurs during the period of bronchial subdivisions. This stage becomes compromised with the major bronchial buds present but the number of bronchial branches significantly reduced in both ipsilateral and contralateral pulmonary specimens.²² Consequently, alveolization is severely affected with significantly fewer normal alveoli at birth.²³

Pulmonary vascular beds are also distinctly abnormal with a reduction in the total number of arterial branches in both the ipsilateral and contralateral pulmonary parenchyma with significant adventitial and

medial wall thickening noted with a resultant increased risk for fixed and intractable pulmonary hypertension.¹ With the institution of breathing, the pulmonary vascular resistance normally decreases allowing for increased pulmonary blood flow. If the pulmonary vascular resistance remains high after the transition to postnatal life, right to left shunting of blood can occur with delivery of unsaturated blood to the systemic circulation with resultant hypoxia. The hypoxia can lead to further increases in pulmonary vascular resistance and compromises to pulmonary flow while increasing right-to-left blood shunting leading to severe and progressive respiratory failure. Postnatally, there is also a failure of the normal arterial remodeling maintaining an abnormally high vascular resistance that is only partially reversible by treatment interventions.²⁴

Based on both experimental work in the laboratory and an understanding of congenital high airway obstruction, the technique of in utero tracheal occlusion was developed to prevent egress of lung fluid and enhance lung growth.²⁵ Although early results did not appear superior to postnatal management,²⁶ Deprest and his group refined the technique and showed promising results compared to historical controls.²⁷ This innovative strategy is being tested in a multicenter randomized clinical trial.²⁸

Congenital Lung Lesions

While CDH results in hypoplasia of the lung due to a disruption of early lung development, other CLLs including congenital pulmonary airway malformations (CPAMs), congenital lobar or segmental emphysema and pulmonary sequestrations (PS) also form space-occupying lesions during fetal development and are often diagnosed prenatally. The exact pathophysiology of CPAM development remains controversial with some authors postulating that it arises from arrested development of localized portions of the bronchial tree during the sixth to seventh week of fetal development while others believe they are hamartomatous lesions of the bronchial tree.²⁹ CPAMs are characterized as a multicystic lung mass resulting from a proliferation of terminal bronchiolar structures with associated suppression of alveolar growth.³⁰ In contrast to CDH, in cases of CPAMs and other CLL, the lung grows and then is compressed by the mass. Consequently, alveolization and bronchial branching is largely preserved in the other areas of the lungs. As a result, following resection or regression there can be normal development of other areas of lung tissue and these patients do not tend to suffer the long-term consequence of prenatal mass effect seen in patients with CDH. The postnatal morbidity and mortality is usually related to the size of the mass.

CPAM and bronchopulmonary sequestration are the most common congenital lung malformations that usually cause no physiologic perturbation prenatally. The natural history and clinical spectrum of these anomalies are variable, but they appear to depend mostly on the size of the mass and the secondary physiologic derangement. The growth of CPAMs usually plateaus between 25 to 28 weeks at which time the fetus appears to grow around the lesion. Most small- to moderate-sized lesions represent 90% to 95% of CPAMs and remain asymptomatic during fetal life. In contrast, large lesions represent 5% to 10% of CPAMs and may produce significant mass effect, which can lead to pulmonary hypoplasia and associated pulmonary hypertension, impaired fetal swallowing and polyhydramnios, and impaired fetal circulation and heart failure. Congestive heart failure in the fetus, known as nonimmune fetal hydrops, is defined by the presence of skin or scalp edema, or by fluid accumulation in two or more serous cavities (ascites, or pericardial or pleural effusions). The risk of hydrops appears to depend on the size and rate of growth of the mass, and results from compression of the SVC and impaired venous return.³¹ In the past, hydrops was considered a harbinger of fetal demise, and was associated with near 100% mortality.³² Rarely, hydrops is due to a tension hydrothorax from extralobar sequestration. As a prognostic factor, the CCAM volume ratio (CVR) has been developed to correlate the relative size of these lesions with fetal and postnatal outcome.³³ In one series in which 58 fetuses with a lung mass were followed prospectively, 75% of fetuses (12 of 16) with CVR greater than 1.6 developed hydrops, whereas only 17% (7 of 42) with CVR 1.6 or less had this complication. However, the CVR was not predictive of hydrops if a CCAM had a dominant cyst which may enlarge at an unpredictable rate. If signs of hydrops appear, the treatment options include percutaneous placement of a thoracoamniotic shunt for lesions with a dominant cyst, maternal steroids, and rarely open fetal thoracotomy and mass resection if the fetus does not respond to steroids. Although not well understood, results from a small series of patients suggest that maternal administration of betamethasone should be first-line therapy for all fetuses with a large lung mass (CVR > 1.6), and for those with hydrops.^{34,35}

Preterm Labor

For every fetal surgery, there is risk of preterm delivery. Chorioamniotic membrane separation and

preterm labor remain the Achilles' heel of fetal interventions.^{36,37} Surgical approaches that involve a smaller hysterotomy and more minimally invasive techniques appear to lower these risks.³⁸ Specifically, fetoscopic and percutaneous approaches lessen the maternal and fetal risks. These techniques allow vaginal delivery after fetal surgery and appear to decrease the incidence of preterm delivery.

Preterm labor is the single biggest concern during the operation and in the postoperative period. The mother receives a 50-mg indomethacin suppository before surgery, and remains on indomethacin for 48 hours postoperatively. Daily echocardiography is essential; if there is evidence of PDA restriction, then the indomethacin is stopped. During the operation, nitroglycerin infusion can be used to help control uterine irritability and enhance relaxation. During closure of the hysterotomy, the mother is given a 6-g bolus dose of magnesium sulfate followed by a continuous infusion of 2 to 4 g per hour for up to 48 hours. Postoperatively the mother is closely monitored for pulmonary edema, fluid management, and uterine irritability. On the second to third postoperative day, usually the magnesium and indomethacin can be weaned, and the patient is converted to oral nifedipine.

Neonatal and Pediatric Physiology

Neonatal and Pediatric Lung Mechanics

The mechanical properties of the lung play an important role in pulmonary mechanics and neonatal respiratory physiology. The lung has physical properties which resist inflation including recoil, resistance, and inertance with the dynamic interaction between these processes being responsible for the effort required during normal spontaneous breathing.³⁹ Elastic recoil is a property of the elastic lung tissue which must be stretched for lung inflation to occur. According to Hooke's law, the pressure needed to inflate the lung must be proportion to the volume of inflation. This relationship of proportionality is change in volume divided by change in pressure or lung compliance. Dynamic compliance is the volume change divided by the peak inspiratory transthoracic pressure. Static compliance is volume change divided by peak inspiratory pressure.⁴⁰ Throughout the range of normal tidal volumes, this relationship is linear and starts to plateau at large lung volumes. On a static compliance curve, ventilation normally occurs in the steep portion where large changes in volume occur for small changes in pressure. This is not true at high or low lung volumes where large changes in pressure are necessary for smaller changes in volume.

The total compliance for the pulmonary system is made up of the compliance of the lung and the chest wall. The relationship can be expressed by the equation: respiratory system compliance (CRS) = $1/\text{chest wall compliance (CCW)} + 1/\text{lung compliance (CL)}$.³⁹ The desire for the lung to collapse is balanced by the outward elastic recoil of the chest wall with FRC occurring at the end of expiration when these forces are in equilibrium. In infants, the chest wall is composed primarily of cartilage and thus the CCW is greater in the infant and the pleural pressure is less negative. As a result of the more compliant chest wall, the neonatal lung appears more prone to collapse.⁴¹ FRC is maintained in newborns by increasing expiratory resistance through laryngeal abduction, maintaining inspiratory muscle activation throughout expiration, and initiating high breathing frequencies to limit expiration time.⁴²

Resistance to gas flow is also an important determinant of pulmonary gas movement in the neonate. Resistance to airflow arises due to friction between gas molecules and the walls of the airway and because of friction between the tissues of the lung and the chest wall. The airway resistance makes up a significantly greater proportion of the resistance making up approximately 80% of the total resistance with 50% of the airway resistance.⁴³ During laminar flow the pressure difference necessary for gas to flow through the airway is directly proportional to flow times a rate constant-airway resistance.³⁹ During turbulent flow, which occurs at branch points, sites of obstruction, and high flow, this pressure necessary to move air is directly proportional to a constant times the flow rate squared. This constant is directly proportional to the volumetric flow rate and gas density and is inversely proportional to the radius of the airway and gas viscosity. Airway diameter is possibly the most important clinical factor effecting airway resistance because airway resistance varies inversely with the radius to the fourth or fifth power. Airway resistance is decreased during inspiration as the pleural pressure becomes negative due to expansion of the chest wall which increases airway and alveolar diameter and decreases resistance. During expiration, the pleural pressure increases and the airways are compressed. Collapse is prevented by cartilage and gas pressure in the lumen which can become a problem especially in small preterm infants with poorly supported central airways.

Work of breathing is the amount of energy required to overcome the elastic and resistive elements within the pulmonary system and move air in and out of the lungs. This is the cumulative product of

distending pressure and the given volume displaced during inhalation or exhalation.³⁹ In neonates, this is approximately 10% of the energy expenditure of an adult and the majority of work is done by the diaphragm. One-third of the inspiratory work is presumed to overcome the resistance of gas flow in the airways.

Evaluation of Lung Function

Knowing the terminology describing static lung measurement is essential to describing pulmonary function (Fig. 99-3). Assessing lung function in the neonates can be difficult as they are unable to cooperate with the examination. However, assessing and understanding lung function is essential to understanding the physiology, pathophysiology, and response to therapeutic intervention. Tidal volume, vital capacity, inspiratory capacity, inspiratory reserve volume, and expiratory reserve volume can be measured directly using spirometer. On the other hand, total lung volume, FRC, and residual volume require specialized techniques. Over the last 50 years, technologic advances have allowed for measurements of neonatal lung function to move from the bench top to the clinic with new ventilators able to provide breath-to-breath analysis of lung function.

The respiratory cycle is determined by changes in pressure which drives air in and out of the lungs. During normal inspiration, the respiratory muscles contract moving the diaphragm inferiorly and chest wall outward resulting in a transient decrease in the transpulmonary pressure from 0 to subatmospheric. This pressure gradient peaks during midinspiration with maximal airflow at that time. It subsequently returns to 0 at the end of inspiration. As the muscles of respiration relax, the inward recoil increases the transpulmonary pressure causing an expiration of inspired air. The airflow again reaches its maximum during midexpiration and returns to zero at the end of respiration. This results in a cycle of pressure within the alveoli from negative to positive pressure during normal inspiration.

Measuring these characteristics of ventilation including pressure, volume, and flows requires specialized equipment and methodologies. Over time, the devices to measure these parameters have continued to significantly improve. Pneumotachometers are one device which can be utilized to airflow. These instruments use gas flow through a tube containing a fixed laminar flow element or flow-resistive-type device. Gas flow across the element causes changes in pressure which can be measured by pressure transducers. An additional means of measuring airflow is the use of hot wire anemometers. These devices measure the amount of current which is required to keep a fine wire a constant temperature with current increasing as airflow increases.^{13,44} Volume measurements can be obtained using a flow sensor and by the integration of the flow signal over time. This is now performed digitally.

New methods to examine lung volumes have been investigated focusing on using techniques which do not require patient cooperation or need to connect to the open airway due to difficulty with leaks and the influence attempts at measurement can have on neonate breathing patterns. For example, one such technique which has been examined and validated in adults is optoelectronic plethysmography which estimates chest wall volume using several three-dimensional markers placed on thorax. This can accurately measure lung volume changes.⁴⁵ In order to obtain meaningful static lung measurements FRC can be measured using whole body plethysmography, however, this is not a practical means for measuring FRC.⁴⁶ Other methods for measuring FRC including helium dilution, nitrogen washout, and sulfur hexafluoride washout, have been utilized but can be challenging in an uncooperative, nonmechanically ventilated infant.

Figure 99-3. Lung measurements: Tidal volume (TV) is the amount of gas moved during one normal inspiration and expiration. Functional residual capacity (FRC) represents the volume of gas left in the lung following normal expiration. Inspiratory capacity is the maximum volume of air which can be inspired following a normal expiration. Inspiratory reserve volume is the additional amount of air which can be inspired following normal inspiration. Expiratory reserve volume is the additional amount of air which can be expired following normal expiration. Residual volume is the minimum lung volume possible, which is the air which remains in the lung following maximum expiration. Vital capacity is the maximum amount of air which can be moved, maximum inspiration following maximum expiration. Total lung capacity is the total amount of volume present in the lung.

Assisted Ventilation

While in most instances, transition from placental support to respiratory self-sufficiency occurs without complications, pediatric surgeons encounter many clinical scenarios where patients require additional assistance and mechanical support of the newborn has been a growing field with many advances. Neonatal respiratory failure has been treated with mechanical ventilation since the 1960s.⁴⁷ Initially, adult ventilators were modified for neonatal use. The first devices designed for neonates were continuous flow, time cycled, pressure limited devices to provide intermittent mandatory ventilation (IMV).⁴⁸ There were many limitations to these ventilators as physicians could only vary fraction of inspired oxygen, peak inspiratory pressure, positive end-expiratory pressure, inspiratory time, rate, and circuit flow. In the 1980s, high-frequency jet ventilation (HFJV) was introduced and has since been widely used. During the 1990s, microprocessors were incorporated into neonatal ventilators greatly expanding the scope of neonatal ventilation with clinicians able to control a greater number of variables including target modality, mode of ventilation, minute ventilation, cycling mechanism, assist sensitivity, and rise time with light weight transducers giving real time breath-to-breath information allowing easier adjustment of ventilator settings depending on patient illness.⁴⁹

Currently, ventilators in clinical use are classified as either those which deliver tidal ventilation (conventional) or devices which deliver smaller gas volumes at rapid rates (high-frequency ventilators). Conventional ventilators have significantly improved over recent years with the addition of the microprocessor chips. They continue to have standard modes of ventilation including IMV, synchronized intermittent mandatory ventilation (SIMV), assist control ventilation (AC), and pressure support ventilation (PSV). These modalities can be further modified to deliver either target pressure or volume. Further description of conventional ventilators is beyond the scope of this chapter, however, the clinical utility of various modalities has been examined in recent literature. For example, a recent meta-analysis of pressure-controlled modalities versus volume-controlled modalities demonstrated a significant decrease in pneumothorax and duration of ventilation as well as a decrease in CLD in preterm infants treated with volume-controlled modes of ventilation as opposed to pressure-controlled modes.⁵⁰

There are two types of high-frequency ventilation: HFJV and high-frequency oscillatory ventilation (HFOV). HFJV provides smaller volumes (1 to 3 mL/kg) more often at a much higher rate (240 to 660 breaths per minute) and expiration is passive. Oxygenation is proportional to mean airway pressure and ventilation is proportional to amplitude (peak inspiratory pressure vs. PEEP).⁴⁸ Jet pulsations produce high-velocity laminar flow which has the ability to bypass airway disruptions. HFOV differs in that it delivers smaller tidal volumes (1 to 2 mL/kg) and at an even faster rate (8 to 15 Hz). The lung is

inflated to a static volume, and then oscillated around the mean airway pressure.

Neonatal and Pediatric ECMO

For infants who cannot be successfully ventilated using these modes of ventilation, extracorporeal life support (ECLS) can become an option. ECLS is indicated in cases of acute cardiopulmonary failure with expected organ recovery which has been unresponsive to maximal therapy.⁵¹ The use of ECLS in neonates is based on the idea that with maximal support native function improves, through natural development or improvement, by application of medical and/or surgical treatments, or transplantation. Three clinical measurement systems have been identified to identify these patients all of which are associated with high mortality risk. However, the decision to initiate this therapy is based on clinical judgment and the patient's response to maximal medical therapy.

Dr. Robert Bartlett and his group had been studying extracorporeal support in laboratory animals for 10 years before the first neonatal extracorporeal membrane oxygenation (ECMO) patient was supported in 1975; this clinical application signified a radical shift in the treatment paradigm for neonatal respiratory failure.⁵² The neonate, Esperanza, was suffering from respiratory failure secondary to meconium aspiration that was recalcitrant to conventional ventilator support. She was successfully supported and now is 37 years old.⁵³

The currently accepted treatment of neonatal cardiopulmonary failure includes low-volume protective ventilation,⁵⁴ inhaled nitric oxide (iNO),^{55,56} surfactant therapy,^{57,58} and HFOV.⁵⁹ If the cardiac or pulmonary failure is refractory to maximal medical therapy then ECMO should be considered.^{60,61} The standard application of ECMO is primarily limited to neonates ≥ 34 weeks EGA and ≥ 2 kg. Clinical experience and laboratory work suggest extracorporeal support may be effective at lower gestational ages by using "Premie ECMO" or the "Artificial Placenta (AP) (Table 99-1)."

Indications

ECLS is indicated for acute cardiopulmonary failure with high mortality/morbidity unresponsive to maximal medical treatment and with expected organ recovery. The premise is that patients can be supported with ECLS while native function improves either by allowing natural development or improvement (lung maturation and surfactant development), application of medical or surgical therapies, or by transplantation. Identification of the patients that can benefit from ECLS can be challenging.

Three clinical measurement systems have been developed and tested to assist in identifying patients that will benefit from ECLS support.

1. *Oxygenation Index (OI)* = $(MAP \times F_iO_2 \times 100) / P_aO_2$ Where MAP = mean airway pressure. This index has been evaluated^{62,63} and shown that an OI > 40 in three to five postductal gases was predictive of a mortality risk $\geq 80\%$.⁶⁴
2. *Postductal Alveolar-Arterial Oxygen Gradient [(A-a)DO₂]* An (A-a)DO₂ of 610 Torr or greater despite 8 hours of maximal medical therapy predicted a mortality of 79%.⁶³
3. *Ventilation Index* = $(Respiratory Rate \times PaCO_2 \times Peak Inspiratory Pressure) / 1,000$

Rivera et al. found that a ventilation index > 40 and OI > 40 were associated with a 77% mortality risk. They also found that the combination of peak inspiratory pressure ≥ 40 cm H₂O and an (A-a)DO₂ > 580 mm Hg was associated with a mortality of 81%.⁶⁵

These clinical measurement systems are useful to quantitate the degree of cardiopulmonary derangement, and subsequently categorize patients into candidates for ECLS therapy or continued maximal medical therapy. However, the decision to initiate ECLS therapy is often a clinical decision based upon clinical judgment and the patient's individual response to maximal medical therapy. Patients are commonly started on ECLS therapy when they have failed maximal medical support, significant barotrauma is imminent, and are felt to have good potential for complete organ recovery.

Classic Contraindications and Possible Treatment Expansion

The classic contraindications to ECLS therapy are listed below. As ECLS treatment evolves and technology advances, many of the classic contraindications to ECLS are being challenged.

1. *EGA less than 34 weeks:* The higher incidence of intracranial bleeding in premature infants has historically precluded the use of ECLS in neonates less than 34 weeks EGA.^{66,67} However, recent data indicate that ECLS can potentially be used in infants as low as 29 weeks EGA with acceptable survival

and intracranial hemorrhage (ICH) rates. Ideally, development of nonthrombogenic coating of circuit components would obviate the need for systemic heparinization and decrease the risk of using ECLS in premature infants.⁶⁸⁻⁷¹

- 2. *ICH greater than grade II:* Neonates with ICH of higher grades are at increased risk of extension of their hemorrhage with systemic heparinization. This remains true today, but the development of technologies that obviate the need for heparinization may allow the use of ECLS in neonates with pre-existing ICH in the future.^{69,71-75} In addition, our experience has suggested that ECMO can be applied when expected mortality is higher in neonates with grade II ICH. In that setting, lower levels of anticoagulation are cautiously applied.
- 3. *Mechanical ventilation for longer than 7 to 10 days:* Classically, mechanical ventilation has been associated with higher incidence of bronchopulmonary dysplasia and irreversible fibroproliferative lung disease. The duration of pre-ECMO mechanical ventilation is being challenged; data from the Extracorporeal Life Support Organization (ELSO) registry demonstrate survival of 50% to 60% after pre-ECLS mechanical ventilation of up to 14 days.⁷⁶
- 4. *Cardiac arrest which requires cardiopulmonary resuscitation (CPR):* Many centers now consider patients who suffer pre-ECLS cardiac arrest candidates for support. Survival rates up to 60% have been demonstrated in neonates who suffer cardiac arrest prior to or during cannulation.^{77,78} Predictably, good outcomes are associated with effective CPR during the resuscitation.
- 5. *Conditions incompatible with meaningful life after therapy – profound neurologic impairment, congenital anomalies, or other conditions:* With improvement in medical and surgical care, conditions once thought to be nonsurvivable require constant reassessment.

Outcomes

Today, ECMO is a part of routine management in the neonatal ICU. Overall survival is 85%, with 98% survival for meconium aspiration and 55% survival for diaphragmatic hernia.⁵² Overall survival after ECLS for neonatal respiratory failure has recently declined. There are likely a few reasons for this decrease in survival. Since its peak in 1992 of 1,500 cases, ECLS has been used with less frequency for critically ill neonates. The fewer number of cases is due to an improvement in other modalities of support such as iNO, HFOV, and surfactant therapy. To some extent, these improvements have been realized as a result of lessons learned from early ECMO experience.^{52,79-81} As a result, the neonatal patients receiving ECLS as the initial form of therapy for cardiopulmonary failure are declining, and the patients that ultimately require ECLS are probably more ill and further along the timeline of their illness.

Table 99-1 ECLS Modality by Age Group

^cStandard of care.

Modalities

ECLS aims to provide perfusion of warmed, arterialized blood into the patient.^{82,83} Traditionally, venovenous (VV) support has been used for respiratory failure while venoarterial (VA) support has been utilized in cases of cardiac or combined cardiopulmonary failure. VV-ECLS can be performed through one-site or two-site cannulation. Traditionally, blood was drained through a cannula placed in the right internal jugular (IJ) vein and returned through the femoral vein, although this approach proved problematic in newborns with small femoral veins. More recently one-site or venovenous double-lumen (VVDL) cannulation has emerged as the preferred cannulation technique. In this mode, a single cannula is placed in the right IJ vein. Deoxygenated blood is drained from one port, pumped through the ECLS circuit where gas exchange occurs, and returned through a separate port on the same cannula into the right atrium. VA-ECLS provides complete cardiopulmonary support. Typically a drainage cannula is placed in the right IJ. Deoxygenated blood is pumped through the ECMO circuit and returned through a cannula in the right carotid artery. Historically, VA-ECLS has been used more than VV-ECLS in the support of neonates. However, data from the ELSO registry demonstrate that the use of VV-ECLS is increasing for neonatal cardiopulmonary failure.⁸³

ECMO II

The first generation of ECMO support devices (known as ECMO I) was used from 1975 to 2008. However, problems with the oxygenator membrane, rotational pump, and cannulae limited expansion of the technology. Recently there has been substantial technologic improvement in ECMO system components and circuitry, defined as ECMO II.⁸⁴

Modern hollow fiber oxygenators have several advantages over the original silicon membrane oxygenators.^{85–87} The hollow fiber design provides a much lower resistance across the oxygenator membrane, allowing for the use of centrifugal pumps in the ECMO circuit. The centrifugal pumps used now consist of a rotating impeller that spins on a small bearing or is magnetically suspended.⁸⁸ Some of the newest pumps available provide pulsatile flow.⁸⁹ Additionally, the advent of the double-lumen Avalon cannula (Avalon Elite, Avalon Laboratories, Rancho Dominguez, CA) allows the percutaneous placement of a single cannula for VV-ECMO support that both drains and reinfuses blood to allow for effective circuit flow.^{90,91} Further, there has been significant research effort put forth to improve the biocompatibility of circuit surface–blood interfaces.^{72,73} Finally, the simplification of operating the ECMO II system makes it such that a trained ICU nurse can manage the circuit. This decreases manpower utilization, as a single ECMO technician may now oversee several patients at once.⁹² These advancements provide translational development in the application and expansion of ECMO support for neonatal cardiopulmonary failure.

ECMO in Premature Neonates

Previous studies have shown poor survival with the use of ECMO in premature neonates. Bartlett's early report of ECLS in 45 moribund neonates, revealed a 55% survival rate for neonates overall. Nine of these patients were less than 35 weeks EGA – two survived (22%). All six who died had ICH.⁹³ A later report showed similarly worrisome survival for premature neonates less than 35 weeks EGA – 33% (3/15). One of these survived with an ICH; the other 12 patients with ICH died.⁶³ A study examining ICH in patients on ECLS showed that all eight of the patients less than 35 weeks EGA had ICH and that six of these died immediately after termination of ECLS while two died within 1 year of age.⁶⁶ Given these poor survival rates (22% to 33%) and the extremely high rate of ICH (75% to 100%), Cilley recommended that the use of ECLS be contraindicated in neonates of less than 35 weeks EGA. However, examination of the ELSO database between 1988 and 1991, found that survival had improved to 63% and ICH rates decreased to 37% for premature neonates born at 34 weeks EGA or younger.^{66,67}

We recently performed a comprehensive analysis of the ELSO database from 1976 to 2008. This analysis showed no statistically significant difference in the risk of IVH in infants 30 to 33 weeks EGA (21%) when compared to those 34 weeks EGA (17%), $p = 0.195$.⁹⁴ The overall survival rate of 54% and ICH rate of 18% for the entire cohort of neonates on ECLS at 34 weeks EGA or younger suggest that the incidence of both mortality and ICH have decreased over time, with a more dramatic reduction observed in ICH. Although the survival for the 29- to 33-week EGA group was significantly decreased (48%) when compared to those patients with EGA 34 weeks (58%, $p = 0.011$), one could argue that these rates are clinically acceptable. Patients born at younger EGA are expected to have a more difficult hospital course. These data suggest that ECLS in the modern era should be explored at EGA as low as 29 weeks with reasonable survival and acceptable rates of ICH.

Rationale for an Artificial Placenta – Applying Fetal Physiologic Principles to the Treatment of Extreme Prematurity. ECMO is increasingly effective for late preterm to term infants (34 to 40 weeks EGA), and it might be beneficial for some infants who are 29 to 34 weeks EGA. However, a different paradigm is required for ECLS in extremely low gestational age newborns (ELGANs, 22 to 28 weeks EGA). ELGANs are at the greatest risk for death and poor long-term outcomes.^{95–97} In particular, respiratory failure in premature neonates contributes to significant mortality and long-term disability. Conventional mechanical ventilation is often inadequate to provide gas exchange and can cause trauma to the under-developed lungs. Even more advanced strategies developed to minimize the trauma of conventional ventilation, including surfactant replacement therapy, nitric oxide inhalation, and HFOV, may at times be insufficient to support these most fragile infants.^{98,99} In theory, the most effective solution is to create an AP that maintains fetal circulation and obviates the need for mechanical ventilation and resultant devastating barotrauma by completely bypassing the lungs.

Definition of the Artificial Placenta

1. Maintenance of fetal circulation and the intrauterine environment
2. No mechanical ventilation

3. Simulated fetal breathing with fluid-filled lungs
4. A novel form of a pump-driven VV or arteriovenous (AV) ECLS/ECMO with outflow via the right jugular vein or umbilical artery, respectively, and inflow via the umbilical vein

A VV-ECLS AP offers several potential advantages over an AV-ECLS system. First, it eliminates the use of arterial vessels that are prone to spasm. Placing a cannula in the right atrium through the jugular vein allows for a passive drainage process that reduces potential negative pressure and cavitation in the circuit. Additionally, VV-ECLS uses the subject's own venous system as a blood reservoir, instead of requiring an external blood reservoir. Another potential advantage relates to the drainage cannula itself. Although it is feasible to advance a large cannula (10 to 12 Fr) through the umbilical artery into the aorta in preterm sheep, this is not possible in premature human infants due to umbilical artery size and vessel anatomy. It would be very difficult to place even a 6-Fr cannula through the umbilical artery of a premature human baby. On the other hand, a larger cannula (6 to 8 Fr) can be inserted into the right IJ vein in premature infants to allow for adequate drainage. Finally, a VV-ECLS AP operates in parallel with the systemic circulation. Similar to traditional VV-ECMO circuits, the fetal heart would experience little increased resistance and afterload from the parallel circuit.^{83,100} Conversely, an AV-ECLS system with an oxygenator placed in series has the potential to increase stress on the fetal heart and contribute to cardiac failure.¹⁰¹

Clinical Prognostic Factors

The ideal patient population to benefit from the AP are ELGANs (<28 weeks EGA) who fail the most aggressive pulmonary therapies, such as low peak pressure ventilation, nitric oxide inhalation, surfactant administration, and HFOV. Early identification of those with the highest mortality risk has been validated in this population using mortality prediction tools (CRIB II and SNAPPE II) based on data obtained in the first 12 hours of life.^{102–104}

Potential Complications and Current Limitations

There are several potential complications and questions that must be addressed in the laboratory before the AP can be taken to the clinical setting. The first, and most pressing, is the issue of anticoagulation and the risk of intracerebral or intraventricular hemorrhage (IVH). Issues with IVH were the main driving force for limiting conventional ECMO to late-gestation newborns.^{67,105} However, many of these reports were from a time before activated clotting time (ACT) was routinely followed in systematically anticoagulated neonates, leading to excessive anticoagulation. More recent studies on the pathogenesis of IVH suggest that many causes may be iatrogenic. The mechanism of injury may be either due to a disruption of cerebral blood flow or injury to the relatively weak endothelial tissue of the germinal matrix.^{106,107} Disruption of cerebral blood flow can be caused by transfusion or rapid volume expansion that leads to increases in arterial pressure and cerebral blood flow, or through positive pressure ventilation that may obstruct venous outflow and result in increased cerebral perfusion pressures.^{106,108} Avoiding ventilation and providing stable hemodynamics and gas exchange might afford the same protection against IVH. Nevertheless, to further minimize the risk of IVH, we propose the eventual use of nonthrombogenic surfaces in the form of biomaterials that release NO to completely eliminate the need for anticoagulation.^{69,71,74,75}

Prematurity

Extremely premature infants are still “fetuses” living outside the womb and the physiology, pathophysiology, and treatment should be viewed through the lens of fetal physiology. Premature birth (<37 weeks EGA) occurs in 11% of births in the United States and remains the leading cause of morbidity and mortality in industrialized nations accounting for 60% to 80% of deaths in infants without congenital abnormalities.¹⁰⁹ Prematurity affects most organ systems and includes temperature instability, respiratory failure and CLD, gastrointestinal problems including necrotizing enterocolitis (NEC), ICH, and sepsis. ICH occurs in approximately 12,000 premature infants every year with 50% to 75% of the survivors developing cerebral palsy, mental retardation, or hydrocephalus and another 25% of the nondisabled survivors developing psychiatric disorders or problems with executive function.¹¹⁰ Prevention, early recognition, and timely management are crucial in decreasing long-term morbidity and mortality.

The more premature the infant, the greater the risk for pulmonary complications with ELGANs born before 28 weeks EGA at greatest risk. As mentioned earlier, these infants are born at the transitional period between the canalicular and saccular phases which is when the air–blood barrier is just beginning

to thin to the point where exchange is possible. Glucocorticoids are administered to mothers undergoing preterm labor after 24 weeks in order to promote surfactant production and maturation of the fetal lung.^{111,112} The exact mechanism remains unknown, however, studies have shown that anatomic maturation, in particular thinning of the alveolar wall, and synthesis of mRNAs encoding surfactant proteins increase with exposure and while with removal mRNAs decrease, anatomic changes persist.¹¹³⁻¹¹⁵

Operating on newborn infants, especially premature, can be technically challenging just by size alone. As the size of the infants can vary from a few hundred grams to several kilograms, surgeons must consider various technical and physiologic aspects of each procedure, choosing the safest and most effective option.

Several developmental and physiologic issues complicate surgery on premature infants. Lack of thermoregulation, inadequate skin integrity, and incomplete immune development are ubiquitous to all premature infants and can affect the morbidity of surgery. These aspects must be considered in all children, but most of all in the smallest patients, when choosing the location for surgery, transportation of the child, skin preparation, use of prophylactic antibiotics, placement of foreign bodies, postoperative wound management, and healing potential. Furthermore, specific physiologic processes inherent to the premature infant further complicate surgical planning.

Propensity for certain physiologic conditions in the neonate increases the risk of morbidity of operating on these children: hypoglycemia, apnea and respiratory distress, and neurologic development. Though patients are commonly kept nil per os (NPO) prior to surgery, to decrease the risk of aspiration with anesthesia, surgeons need to assess the risks and benefits of this approach for neonates who are at significant risk for hypoglycemia. As line access for neonates may be tenuous and difficult to obtain, liberal use of enteral nutrition, appropriate timing of surgery, and early resumption of feeds in this population should be thoroughly considered. Furthermore, the use of narcotics and sedation can increase the risk of postoperative apnea and respiratory distress. The edema in the neonatal airway from intubation can contribute to early postoperative morbidity and need for reintubation or positive pressure ventilation; therefore, a conservative approach to extubation and postoperative monitoring should be used. Finally, although controversial, multiple studies suggest deleterious effects of anesthesia on the developing neonate and some recommend postponing elective procedures until children are 3 years of age.¹¹⁶⁻¹²⁰

Thermoregulation

Fetal thermoneutrality is maintained in a warm intrauterine environment where the amniotic fluid reflects the maternal core temperature. In addition, the fetus generates 3 to 4 W/kg heat through an oxygen consumption of 8 mL/min/kg.¹²¹ The placenta eliminates 85% of fetal heat into the maternal circulation, the remaining 15% is dissipated through conductance to amniotic fluid and to the uterine wall. The fetus is at 0.5°C to 1.0°C above the maternal core temperature.

In neonates, thermoneutrality is defined as an axillary temperature between 36.7°C and 37.3°C.¹²² Soon after birth, approximately 135 to 155 W/m² of heat loss can occur through evaporation, radiation, convection, and conduction.¹²¹ Therefore, a newborn exposed to cold stress must mount a variety of responses to conserve heat loss, increase heat production, and maintain core temperature. The main source of heat production is brown adipose tissue, which peaks at term gestation, used for nonshivering thermogenesis. Term newborns also increase involuntary activity, and have hypothalamic-regulated vasoconstriction to maintain thermoneutrality.^{13,121}

Prematurity leads to insufficient brown fat for nonshivering thermogenesis, a larger surface area to body mass ratio, deficient subcutaneous fat and nonkeratinized thin skin, decreased ability to maintain flexion of extremities, and underdeveloped response of temperature sensors in the posterior hypothalamus to release thermogenic hormones (thyroxine and epinephrine).¹³ In low-birth-weight infants, the use of a servoregular set to 36°C has been shown to increase survival as compared to setting a constant incubator temperature. Radiant warmers increased insensible water loss and did no better when compared to incubators for temperature control.¹²³

Neonates needing surgery are frequently transported to and from the neonatal ICU to the operating room and radiology, leading to increased risk of heat loss. Furthermore, since fever is an infrequent sign of postoperative infection, monitoring for temperature instability is more effective. Finally, perioperative issues such as intraoperative irrigation, exposure during positioning, skin preparation, and operating room temperature can all have ill effects on the susceptible neonate's thermoregulation.

Skin Integrity

In addition to augmenting the risk of infant heat loss, poor skin integrity of neonates, especially the low

birth weight or premature, has its own impact on the surgical patient. Beyond thermoregulation, the thin, underdeveloped skin has several other challenges including the use of local anesthetic, skin preparation, immune properties, bathing and wound care, and the use of an adhesive dressing. Skin provides mechanical protection, maintains thermoregulation, provides immunosurveillance, and prevents insensible loss of body fluids.¹²⁴ Skin of premature infants is thinner and more dysfunctional. The inadequate epidermal barrier allows increased water loss, absorption of chemicals, and trauma causing difficulties with fluid homeostasis, thermoregulation, infection, and toxicity.¹²⁵

Iatrogenic injury and alteration in skin integrity can occur more often in premature infants due to several factors. At 26 weeks, the developing epidermis is only 2 to 3 cells thick. At 28 weeks, the skin is deficient in fat and zinc, increasing the potential for infection, damage, and injury.¹²⁶ Furthermore, due to the lack of protein in the subcutaneous layer, increased edema can form in the skin from excess water and sodium. The lack of sweat glands, a reduced blood supply, and lack of fat and calorie reserves, result in an increased risk of hypothermia.¹²⁶

At birth, the baby's skin is coated with vernix caseosa (a gel like substance that has antibacterial properties) in addition to blood, meconium, and cellular debris. The baby should not be bathed in the first 6 hours due to increased risk of hypothermia. Premature infants should have a bathing schedule approximately once every 4 days.¹²⁴ In fact, bathing has been shown to reduce skin colonization, which may increase the risk of pathologic infection. Meticulous umbilical cord cleansing in the first 1 to 2 weeks, however, can markedly reduce infection and neonatal death. Emollients containing a physiologic balance of epidermal lipids – such as cholesterol, ceramide, palmitate, and linoleate – are optimum for barrier repair.¹²⁷

Due to specific properties of neonatal skin, preoperative preparation should be carefully approached. Since neonatal skin is relatively impermeable to alcohol, it may develop skin burns and necrosis particularly in premature infants when topical antiseptic is used on skin.¹²⁴ Therefore, alcohol-containing skin-cleansing solutions should be used with extreme caution in neonatal units. Iodinated skin disinfectants can result in significant iodine overload and severe transient hypothyroidism. Neonatal iodine exposure should be minimized whenever possible and in cases of exposure, thyroid-stimulating hormone level should be routinely measured.¹²⁸ In general, we use betadine for most neonatal procedures, and chlorprep with hardware implantation (such as central line insertion), though no consensus currently exists.

Use of topical anesthetic similarly can cause systemic toxicity from absorption. Prilocaine, a component of topical anesthetics, can cause methemoglobinemia and cyanosis in neonates. Tetracaine gel can cause contact dermatitis.¹²⁴ Furthermore, the use of lidocaine or marcaine in the subcutaneous space needs to be carefully monitored for overdose. We have used pumps that administer local anesthesia to the incision to limit systemic narcotic use in neonates with modest success.

Dressing the surgical wound in the neonate can create its own challenges. In premature infants, epidermal stripping secondary to tape and adhesive dressing removal is common and the primary cause of skin breakdown in babies in the neonatal intensive care units (NICU). On the other hand, adhesive removers should be avoided due to risk of skin injury and subsequent absorption.¹²⁹ We routinely use steristrips as the sole dressing in children; alternatively skin glue can be an adequate dressing protecting the wound from friction and body fluids (urine, emesis, or feces). For open wounds, the use of a vacuum-assisted device (WoundVac) has been described and can be used selectively.^{130–132} For delicate skin, the use of Duoderm and Montgomery straps with wet-to-dry dressings is a good option.

Infection and Immune Response

Infection is the leading cause of mortality among infants in the first days of life,¹³³ with mortality related to neonatal sepsis responsible for 40% of the annual 3 million worldwide neonatal deaths.¹³⁴ Severe infections occur at a higher incidence and have greater mortality in very low-birth-weight premature neonates, especially in the first 3 to 7 days of life.¹³⁵ Early-onset sepsis, associated with *Escherichia coli* or group B streptococcus (GBS), typically occurs within the first 24 hours, while late-onset sepsis, associated with nosocomial coagulase-negative *Staphylococcus epidermidis*, typically occurs after the first 72-hour period, and is most prevalent among very low-birth-weight babies.¹³⁶ In neonates, central venous catheters are arguably the largest risk factor for neonatal nosocomial sepsis as coagulase-negative *Staphylococcus* and other organisms are the most commonly isolated late-onset pathogens, as they normally colonize the skin around the site or are acquired from the hands of the staff caring for the child.¹³⁷

Maternal factors contributing to the risk of neonatal sepsis include prematurity, low birth weight,

rectovaginal colonization with GBS, prolonged rupture of membranes, maternal intrapartum fever, and chorioamnionitis.¹³⁵ Postnatal factors associated with an increased risk of sepsis include male gender, birth weight <1,000 g, hypogammaglobulinemia, intravenous alimentation, central venous catheters, the use of steroids or drugs that decrease gastric acid acidity, and prolonged duration of mechanical ventilation.¹³⁵ Although the predominant agents are bacterial, viruses including herpes simplex and enteroviruses, can cause fatal neonatal sepsis.¹³⁵ Invasive fungal infections can also contribute to mortality. Human milk, however, contains lactoferrin, an iron-binding glycoprotein that is important for innate immune host defenses at birth because it exhibits broad-spectrum antimicrobial activity and prevents invasive fungal infections.¹³⁸ Neonates with sepsis may present in or progress to septic shock, exemplified initially by cardiovascular dysfunction requiring fluid resuscitation or inotropic support.¹³⁹

Neonates, especially those that are premature, have an “immature” innate immune system, both quantitatively and qualitatively. For example, neonatal neutrophils have three- to fourfold less bactericidal permeability-increasing protein per cell than do adult neutrophils.¹⁴⁰ The low immunologic profile of the newborn infant is possibly a reflection of the demands of the fetal environment, which is inherently considered sterile, and the need to avoid immune responses to maternal antigens.¹³⁶ The development of neonatal immunity is influenced by multiple factors including “maternal cytokines, antigen exposure, and precursor frequency of lymphocytes and antigen presenting cells.”¹³⁸

Neonates have dampened T-helper (Th) responses compared with adults. In fact, many murine and clinical studies have demonstrated decreased Th1-polarizing/proinflammatory responses (TNF- α , IFN- γ , IL-12p70, IFN- α , IFN- γ), with increased production of Th2 polarizing (e.g., IL-6) and anti-inflammatory cytokine production (IL-10), following in vitro stimulation with bacterial products or septic challenge.¹³⁶ This inherent bias toward Th2-cell polarizing cytokines and suboptimal Th1 responses and B-cell differentiation increases neonate susceptibility to acute respiratory and diarrheal diseases.¹³⁸

Toll-like receptors (TLR), a type of pattern recognition receptors, exist on innate immune cells, leading to “second messenger-specific intracellular signaling cascades [sic] that result in gene expression, cytokine/chemokine production, and cellular activation.”¹³⁶ Lipopolysaccharide (LPS, endotoxin) on gram-negative bacteria is a key mediator of systemic inflammation, septic shock, and multiorgan failure and death.¹⁴¹ TLR4, a receptor for LPS is critical for innate immune activation in leukocytes and is expressed on many epithelial cells. Neonatal leukocytes also demonstrate decreased responsiveness to LPS that signals through TLR4.¹³⁶ LPS signals primarily through TLR4 in conjunction with the cell surface adaptor proteins CD14 and MD265.¹³⁵ Cord blood monocytes exhibit higher expression of microRNA 146a (which regulates TLR4 signaling through the inhibition of IRAK4 – critical for downstream signaling) and appear to have higher endotoxin tolerance. Neonatal cord blood leukocytes also demonstrate reduced MyD88 expression and impaired LPS-induced p38 MAPK phosphorylation and LPS-induced proinflammatory cytokine production.¹³⁶ These functional consequences of TLR activation in neonates are so markedly different from those in adults.

Figure 99-4. Zones of injury in ROP.

At birth, the number of neutrophils ranges from 1.5 to 28×10^9 cells/L blood, compared to steady-state levels of 4.4×10^9 /L in adults.¹⁴² Neonatal neutrophils also have lower surface expression levels of TLR4; therefore, the downstream signaling through MyD88 and p38 pathways are defective in neonates following stimulation. Adherence of neonatal neutrophils is impacted by “low levels of cell surface L-selectin and Mac-1 (CD11b/CD18) which mediate the initial loose adhesion and subsequent tight binding of neutrophils to vascular endothelium,” a 50% reduction in transmigration of neonatal

neutrophils to sites of infection.¹³⁸ Newborn neutrophils also exhibit a dramatic reduction in chemotaxis due to “blunted intracellular calcium influx and altered actin polymerization,”¹³⁸ limiting the ability of neutrophils to deform and penetrate the vascular endothelial lining.

Innate phagocyte function is impaired and neonatal neutrophils produce decreased extracellular traps, which phagocytes use to localize and contain pathogens.¹³⁶ The ability to degrade these pathogens is also further compromised due to the defective NADPH oxidase system and inability to generate hydroxyl radicals due to reduced lactoferrin and myeloperoxidase granules. Overall, these defects in neutrophil amplification, mobilization, and function make neonates particularly susceptible to sepsis.¹³⁸

Antibody responses in neonates after vaccine administration are also diminished secondary to poor humoral and/or memory T-cell responses. Pertussis, for example, only produces humoral responses at 3 weeks of life, but not in newborns. Other vaccines, such as those for *Streptococcus pneumoniae* and *Haemophilus influenza*, require multiple boosters. Although, having ability to administer these vaccines at birth would be ideal, these vaccines are only effective a few months later.¹³⁶

In our practice, we routinely use prophylactic antibiotics in neonates due to their immature immune response and susceptibility to sepsis and septic shock. Furthermore, we favor a conservative approach to decrease postoperative complications from infection and wound-healing issues due to the impaired abilities of the neonate. When possible, elective procedures should be delayed to allow for immune development preventing further morbidity.

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is a disorder of low-birth-weight premature infants that could potentially lead to blindness due to damage of the developing retina. In nearly all term infants, the retina and retinal vasculature is fully developed, so ROP does not occur. In preterm infants, retinal development is incomplete and based on degree of immaturity, is at variable risk for damage.

The damage occurs in an orderly fashion progressing from zone 1 (most posterior) symmetrically surrounding the optic nerve head (the earliest to develop). A larger retinal area is present temporally (laterally) rather than nasally (medially) (zone III). Only zones I and II are present nasally (Fig. 99-4).

As ROP progression is orderly, timely recognition and treatment can decrease the risk of visual loss. See Table 99-2 for the schedule for detecting ROP before required treatment based on gestational age at birth.

Table 99-2 Timing of First Eye Examination Based on Gestational Age at Birth

Gestational Age at Birth (wks)	Age at Initial Examination (wks)	
	Postmenstrual	Chronologic
22 ^a	31	9
23 ^a	31	8
24	31	7
25	31	6
26	31	5
27	31	4
28	32	4
29	33	4
30	34	4
Older gestational age, high-risk factors ^b		4

Shown is a schedule for detecting prethreshold ROP with 99% confidence, usually before any required treatment.

^aThis guideline should be considered tentative rather than evidence based for infants with a gestational age of 22 to 23 wks because of the small number of survivors in these postmenstrual age categories.

^bConsider timing based on severity of comorbidities.

Though peripheral retinal cryotherapy is effective in decreasing the rate of structural and visual outcomes, peripheral retinal ablation using laser photocoagulation has similar results and is the preferred method of ablation.¹⁴³ Prevention of ROP using lower oxygen saturations (approximately 85%) was historically advocated for premature infants; however, recent randomized clinical trial has called the practice into question due to the increased mortality with the lower threshold¹⁴⁴ and a higher level of saturation (88% to 92%) is now commonly targeted.

Cardiac Physiology

The unique aspects of neonatal cardiac physiology, pathophysiology, and treatment approaches will be highlighted. As children become adolescents, the cardiac physiology and treatment strategy approximate adults.

5 The neonatal myocardium is immature with less cellular and structural organization, less contractile proteins, and less compliance. The CO equals the heart rate (HR) multiplied by the stroke volume (SV). The SV is dependent upon preload, myocardial contractility, and afterload. In the neonate, the response to volume on the Frank–Starling curve is attenuated compared to mature myocardium. Thus, the neonatal heart increases its CO primarily through increases in HR. Although HRs about 200 are sometimes poorly tolerated due to short filling times, caution should be employed when considering slowing the heart pharmacologically in a sick or stressed infant. The neonatal heart that is volume overloaded cannot respond to catecholamine inotropic support with the usual increase in contractility, and it often responds better to diuretics and afterload reduction. The normal HRs of infants and children are shown in [Table 99-3](#).

Unlike mature cardiac muscle, the neonatal myocardium has an underdeveloped sarcoplasmic reticulum and is more dependent on extracellular calcium sources. Significant decreases in contractility and subsequent hypotension can be observed when ionized calcium levels fall, and the drop can be acute and dramatic. Careful attention to neonatal ionized calcium levels is essential in the perioperative period, particularly when neonates are not being fed enterally, are stressed or septic, are on loop diuretics that promote calcium loss such as furosemide, or have conditions associated with hypoparathyroidism or hypocalcemia, such as DiGeroge syndrome.¹⁴⁵

6 Bradycardia can arise from the atrium or the ventricle. In neonatal resuscitation, bradycardia is concerning when the HR is less than 100 bpm. The primary cause of neonatal bradycardia is hypoxia. As such, the treatment begins with assessment of the airway and measures to oxygenation and ventilation. If the HR decreases below 60 bpm despite adequate oxygenation and ventilation, chest compressions are indicated followed by administration of epinephrine 10 mcg/kg intravenously. Other causes of sinus bradycardia include hypothermia, hypothyroidism, electrolyte disturbances (hypokalemia, hypercalcemia, and hypermagnesemia), and medications. If there is hemodynamic stability, treatment addressed the underlying cause.

Table 99-3 Normal Range of Awake and Sleeping Heart Rates in Infants and Children

Age	Awake Heart Rate (bpm)	Sleeping Heart Rate (bpm)
Neonate	100–190	80–160
Infant	100–180	75–160
Toddler	80–140	60–90
Preschooler	70–120	60–90
School age	65–110	60–90
Adolescent	60–100	50–90

Table 99-4 Normal Range of Blood Pressure in Infants and Children

Age	Systolic Pressure (mm Hg)	Diastolic Pressure (mm Hg)
Neonate	50–70	25–45
Infant	70–100	50–70
Toddler	80–110	50–80
Preschooler	80–115	50–80
School age	80–120	55–80
Adolescent	90–130	60–88

Tachycardia can arise from the atrium or ventricle. Sinus tachycardia can occur from hyperdynamic states such as sepsis, fever, seizures, thyrotoxicosis, pain, and hypoglycemia. Treatment is aimed at the underlying etiology. Tachyarrhythmias include atrial flutter, atrial fibrillation, and paroxysmal atrial tachycardia. Supraventricular tachycardia can be ectopic with variable rate and respond to esmolol, sotalol, or flecainide but reentrant SVTs usually have a fixed rate and respond to adenosine. Ventricular tachycardia and SVTs with hemodynamic instability should be cardioverted.

Clinical perfusion endpoints in term neonates include a capillary refill time of <2 seconds, normal pulses without differential between peripheral and central pulses, warm extremities, urine output greater than 1 mL/kg/hr, low serum lactate, and mixed venous saturation of >70%.¹⁴⁶ In premature neonates, the mean arterial pressure (MAP) should be greater than or equal to 30 mm Hg.¹⁴⁷ However, a gestational age-based cutoff for “normal” blood pressure (goal MAP > GA) is used at many tertiary centers, especially in the first 3 days after birth (Table 99-4).¹³⁷

In term or older preterm infants, hypotension is generally managed with volume expansion (using 20 mL/kg of an isotonic solution with a repeat bolus as needed). In contrast, rapid volume expansion in extremely premature infants has a significant risk of ICH in the first few days of life.¹⁰⁸ Therefore, in hypotensive premature neonates, after a single bolus of saline (10 mL/kg over 60 minutes), vasoactive medications may be started.^{148,149} In cases of obvious acute volume loss in preterm infants, more volume may be needed in addition.¹³⁶

Dopamine (5 to 10 µg/kg/min) is generally the first vasoactive drug for neonates with shock.¹⁴⁹ Patients with depressed myocardial function may benefit from infusion of dobutamine for both inotropy and vasodilation. Dobutamine improves and maintains systemic blood flow better than dopamine but can increase myocardial oxygen demand in high doses due to its chronotropic effect.¹⁵⁰ With persistent hypotension, glucocorticoids such as hydrocortisone,¹⁵¹ vasopressin,¹⁵² or other inotropes/vasoactive agents may be needed. Epinephrine or norepinephrine infusions for refractory shock in neonates have been studied to a very limited extent and should be considered for vasodilatory shock. Addition of these agents (after fluids and dopamine/dobutamine) can improve blood pressure, reduce tissue lactate, increase cerebral blood volume, and cerebral oxygen delivery in VLBW infants.^{153,154} Milrinone, a phosphodiesterase inhibitor and potent pulmonary and systemic vasodilator, has not been well studied in neonatal septic shock but is commonly used in pediatric patients with septic shock to increase cardiac index, SV, and oxygen delivery while decreasing systemic vascular resistance without increasing HR or blood pressure.^{150,155} Figure 99-5 demonstrates the management of neonatal and pediatric septic shock.

Congenital Heart Disease

Major neonatal cardiac abnormalities can be defined into two broad categories: acyanotic and cyanotic. Acyanotic diseases do not present with hypoxia at birth and can be monitored over the next several months. These conditions are grouped into those that increase pulmonary vascularity (from overcirculation through the pulmonary vascular system) and those with ventricular tract outflow obstruction.

7 Ventricular septal defect (VSD) is the most common heart defect occurring in nearly a third of neonates with congenital heart disease, presenting at 2 to 6 weeks with a left-right shunt (depending on size of the defect). Occasionally, neonates can present with Eisenmenger syndrome from a large VSD and pulmonary vascular obstructive disease (either from an anatomic obstruction or persistent pulmonary hypertension at birth), with resultant right-to-left shunt, cyanosis, and impending death. These patients also have pulmonary hemorrhage, infections, and/or paradoxical emboli crossing over. Surgical indications for VSD include uncontrolled congestive right heart failure, increased pulmonary vascular resistance, failure to thrive despite maximal medical therapy with diuretics and fluid restriction, recurrent pulmonary infections, endocarditis, or paradoxical emboli.

Atrial septal defect (ASD) is the third most common, occurring in approximately 8% to 10% of patients with congenital heart disease. The symptoms depend on the size of defect and the relative compliances of the right and left ventricles. Surgical indications include right ventricular overload, arrhythmias, paradoxical emboli, and elevated pulmonary vascular resistance. AV septal defects, occurring more commonly in patients with Down syndrome, can have symptoms of either VSD or ASD and surgery is performed at 3 to 6 months to prevent consequences of pulmonary hypertension.

8 A PDA is when the connection between pulmonary artery to the descending aorta does not close spontaneously in the first weeks of life. Symptoms (left-to-right shunt) depend on the size of PDA and pressures in descending aorta and pulmonary artery. Fluid restriction is the first line of therapy when appropriate with indomethacin reserved for persistent cases to help stimulate closure. In a few patients, the duct will need to be ligated when symptomatic and not responsive to nonoperative measures.

Acyanotic cases with ventricular outflow tract obstruction can occur in aortic stenosis, coarctation of the aorta, and pulmonic stenosis. In aortic stenosis, the commissures of the valve are fused and surgery is indicated with the annulus is small and balloon valvuloplasty is unsuccessful. Coarctation can present with shock in the first week after the DA spontaneously closes, and is managed with prostaglandin E1 to keep the ductus open prior to surgical repair. Postoperatively, systemic hypertension is managed with beta blockade. Pulmonic stenosis is the second most common cardiac disease and is secondary to the fusion of commissures. It is treated with balloon valvuloplasty or surgery and valve replacement.

Cyanotic heart diseases with decreased pulmonary vascularity include tetralogy of Fallot and tricuspid atresia. Tetralogy of Fallot accounts for 7% of all cardiac defects but is the most common cyanotic CHD. The tetralogy is defined by (1) pulmonic stenosis, (2) VSD, (3) aorta overriding ventricular septum, and (4) right ventricular hypertrophy. Classic “tetralogy spells” are due to elevated pulmonary pressures and subsequent diversion of flow from pulmonary to systemic circulation, and resultant hypoxemia. Infants further develop irritability, hypercapnia, and cyanosis. Treatment consists of knee-to-chest position, oxygen, morphine, IV fluid, bicarbonate, and transfusion for anemia. Surgery is indicated for increasing cyanosis or frequency of episodes.

Tricuspid atresia is a rare defect. The tricuspid valve lacks patency, and usually is associated with an ASD or foramen ovale and a hypoplastic right ventricle or pulmonary outflow tract unless a VSD is also present. The treatment consists of using a prostaglandin infusion to maintain DA patency, a modified Blalock–Taussig shunt in the first week of life, modified bidirectional Glenn anastomosis (SVC to right PA) at 6 to 9 months of age. A modified Fontan at 2 years of age is used to completely bypass right heart with flow from SVC/IVC to PA.

Cyanotic heart diseases with increased pulmonary vascularity include transposition of the great arteries, truncus arteriosus (TA), total anomalous pulmonary venous connection, and hypoplastic left heart syndrome (HLHS). In transposition of great arteries, the aorta arises from right ventricle and pulmonary artery from the left. The treatment is a stepwise approach with the use of a prostaglandin infusion, followed by balloon septostomy and repair of the defect in the first week of life with an arterial switch operation to reconnect each artery with the proper ventricle.

TA is a rare defect with a single vessel above both right and left ventricles with a large VSD. The common vessel – TA – gives rise to the aorta, coronary arteries, and pulmonary arteries. TA is associated with the DiGeorge sequence (thymic hypoplasia, third and fourth pharyngeal pouch syndrome) and patients should be evaluated for hypocalcemia (hypoparathyroid) and T-cell immunodeficiency (with only irradiated blood transfusions given to prevent graft-vs.-host disease). To repair the defect, a conduit is created from right ventricle to pulmonary arteries with separation from the TA which supplies the cardiac and systemic circulation. The VSD is also closed to allow for the left

ventricle to empty into the TA.

Total anomalous pulmonary venous connection involves an abnormal connection of pulmonary venous to systemic venous connections creating a cyanosis. Three subtypes exist: supracardiac to innominate vein, intracardiac to coronary sinus, and infracardiac below diaphragm to hepatic, portal, or umbilical venous systems. All subtypes require surgical repair upon presentation.

HLHS consists of stenosis of mitral and aortic valves, coarctation, and as the name suggests, a hypoplastic left ventricle. HLHS presents with cyanosis and shock when the DA closes and the management, similar to TA, is with a prostaglandin infusion to reopen the duct. Surgical correction includes a Norwood procedure, which includes the Blalock–Taussig shunt, followed by a Glenn procedure at 3 to 6 months and a modified Fontan at 2 years.

Renal Physiology

In utero, the fetus is nearly all water (94%) early in gestation and gradually decreases to 78% by term, though most of the volume is still extracellular. Over the following week, another 3% to 5% reduction occurs. Total body water continues to decline over the next year and a half (mostly in the extracellular component) to approximately adult levels (60%). In premature infants, both fetal and neonatal excess fluid is unloaded within the first week.

9 The glomerular filtration rate in neonates is lower than adults but quickly increases from 21 to 60 mL/min/1.73 m² by 2 weeks and reaches adult levels by a year and a half. Furthermore, an infant enduring water deprivation can only increase urine osmolality to 600 mOsm/kg, whereas adults can concentrate to 1,200 mOsm/kg. Insensible water losses which decrease over time can be excessive in preterm infants. Transepithelial water diffusion through the skin and through humidified inspired air from the lungs can be greater than 120 mL/kg/d.

A neonate's weight can be the best indicator of fluid status with the birth weight used to calculate fluid/medication rates until a return to birth weight in 1 to 2 weeks. In premature infants insensible losses from the respiratory tract account for 30%. From 1,500 to 2,500 g, fluid losses decrease from 30 to 60 mL/kg/d down to 10 to 15 mL/kg/d by about half with each 500 g increase in weight. In patients with an ostomy, a nasogastric tube for drainage or increased stool output from malabsorption, there may be substantial fluid and associated sodium losses that need to be accounted for in the administered fluid.

Neonatal fluid requirements should be calculated using a combination of metabolic demands, pre-existing fluid deficit, and continuing losses. Following a neonate's urine output and concentration to achieve an isotonic level of 280 mOsm/L, can help guide fluid administration. Augmenting this information with frequent monitoring of serum sodium, BUN, creatinine, and osmolality, and urine sodium, creatinine and osmolality allow titration of fluid to the infant's response. In neonates with a decreased urine output despite appropriate fluid administration, calculating a FeNa (fractional sodium excretion) using the ratio of urine:serum sodium:creatinine values, helps differentiate prerenal causes (FeNa < 2) from acute tubular necrosis (FeNa > 3).

Hypo- and hyponatremia are defined as values below 130 mmol/L or above 150 mmol/L, respectively and reflect overall body fluid composition. With high urinary losses, hypoxic injury, or diuretic use, there may be excessive sodium loss leading to hyponatremia. The replacement should be done slowly over 24 to 48 hours by calculating the deficit ($[\text{desired level} - \text{actual level of sodium}] \times \text{weight in kg} \times 0.6$) and adding it to the maintenance fluid accounting for insensible losses. In low-birth-weight infants, preemptively adding sodium enterally can be useful to prevent hyponatremia and help with weight gain and growth.

Water retention can also lead to hyponatremia with excess dextrose solutions, renal failure or congestive heart failure with fluid restriction usually the first-line treatment and rarely using hypertonic saline if symptomatic to correct serum levels to 125 mmol/L. Occasionally, using diuretics can help with excess fluid removal but at the cost of other electrolyte losses (potassium, calcium, magnesium).

With dehydration, and with renal or gastric losses, the sodium may actually rise with fluid deficits in the 10% to 15% range. The correction should be done with caution over the next 24 to 48 hours by calculating the water deficit ($[1 - (\text{serum sodium}/140)] \times \text{weight in kg} \times 0.6$). If the patient is symptomatic (shock), resuscitation using 10 to 20 mL/kg saline from the total water deficit could be helpful. Using hypotonic fluid can be deleterious if the cause is hypovolemia and replacement with normal saline could correct the hyponatremia along with shock. In patients with hypervolemic hyponatremia, the use of loop diuretics can help with removal of excess fluid and sodium.

Nutrition and Gastrointestinal Physiology

10 A term newborn grows at 25 to 30 g/d over the first 6 months, doubling their birth weight by 5 months, tripling it by 12 months, four times the weight by 3 years, and a 20-fold increase over the first decade.¹⁵⁶ The body length increases by half in the first year and triples in the first decade. To sustain this pace of growth, calorie supplementation in the neonate and premature infant is paramount.

The pace of growth for the preterm infant (less than 27 weeks) is substantially slower at 10 to 20 g/d prior to the accelerated growth seen in the third trimester.¹⁵⁷ Moreover, fat accounts for nearly 16% of the birth weight in the term infant; whereas the premature infant has only 1% to 2% fat. Furthermore, the premature infant loses nearly 15% of its birth weight in the initial 1 to 2 weeks of life. In contrast, a term baby only loses about 7% to 10% of its weight. Therefore, though the caloric need remains high, the growth rate and gestational age must be closely accounted for when providing said calories.

Assessment of caloric need in the surgical baby is further complicated by (1) a potentially dysfunctional GI tract, (2) wound healing needs, and (3) any weight loss and malnutrition prior to surgery. Anticipating postsurgical caloric needs begins with a subjective assessment of weight loss, vomiting, fluid status, and muscle wasting, along with objective measures of weight on a standardized growth curve, and differentiating chronic malnutrition using weight-to-height and head-circumference measures. Biochemical measures such as albumin, prealbumin, and retinol-binding protein can be inaccurate as do not have age-based norms, and can fluctuate with surgery and increased metabolic demand.¹⁵⁸ Bone age can be a useful measure for chronic malnutrition; however, can also be affected with long-term TPN use in the surgical patient.¹⁵⁹

As stated above, the energy needs of an infant vary by age and physiologic status. The recommended daily calories and protein needs can fluctuate – therefore, the health care provider must carefully monitor weight gain, fluid status, and changes in body morphometrics to determine if the provided calories match the needs of the baby. The most accurate method of measuring energy expenditure, however, is indirect calorimetry.¹⁶⁰

The primary enteral carbohydrate delivered to neonates is lactose.¹⁶¹ Lactase – the enzyme that breakdown lactose – is commonly found in high levels in most children below the age of 3. Nonlactose formulas are usually soy based and contain sucrose or corn syrup. Premature infants may not have adequate lactase levels; therefore hydrolyzed mixtures with lactose and glucose polymers are commonly provided.

Fats are an excellent source of energy (providing 9 kcal/g) and essential fatty acids. Withholding lipids from a neonate can lead to fatty acid deficiency within 3 days.¹⁶² Manifestations of fatty acid deficiency include scaly skin, hair loss, diarrhea, and impaired wound healing.¹⁶³ Intralipid given with parenteral nutrition, however, can also lead to liver disease and decreasing the amount given while monitoring for fatty acid deficiency has been shown to decrease development of cholestasis.¹⁶⁴

Of the 20 amino acids identified, 9 are considered essential in neonates. New tissue cannot be formed unless all the essential amino acids are present in a diet simultaneously! Furthermore, these protein requirements are higher in term neonates and infants (2 to 3 g/kg/d) than children, and even higher in preterm infants (3 to 3.5 g/kg/d).¹⁶⁵ The added protein needs, however, must be balanced with development of uremia secondary to the immature kidney.

While the energy needs must be met using carbohydrates (50%), fat (35%), and protein (15%), the fluid requirements, minerals and vitamin needs, and, trace elements must also be managed. Water content of infants is 75% of the body weight compared to 60% in adults. In term neonates and preterm infants, water makes up an even higher percentage. The daily consumption of fluid is nearly 10% to 15% of their body weight; compared to 2% to 4% in adults.

11 The enteral nutrition of choice is breast milk even in the premature or very low birth weight (VLBW, less than 1,500 g) infant. The American Academy of Pediatrics recommends exclusive breastfeeding for the first 6 months of life and continued breastfeeding for a year or more with the introduction of solid foods.¹⁶⁶ Benefits of human milk include “enhanced host defense, neurologic development, and gastrointestinal function.”¹⁶⁷ Human milk decreases the incidence and severity of nosocomial infections and NEC, improves visual acuity and cognitive development,¹⁶⁸ enhance gastric motility and increases gastric emptying time allowing the infant to absorb nutrients more efficiently, stimulates gastrointestinal growth and maturation, and provides protection of the gastrointestinal mucosa, and decreases risk of feeding intolerance.¹⁶⁹

The human-milk-fed premature infant might, however, still require nutrient supplementation, or fortification, to maintain optimal nutritional status. Furthermore, despite hospital-grade double electric breast pumps to initiate and maintain milk supply, pumping mothers struggle with low milk supply.¹⁷⁰ Neonatal and infant formulas are commonly used as substitutes for human breast milk. Infants receiving

formula, however, are 6.5 times more likely to develop NEC than those infants receiving human milk diets alone. Use of donor human milk has been demonstrated “to decrease morbidity, nosocomial infections, NEC, urinary tract infections, gastroesophageal reflux disease, diarrhea, and length of hospital stay.”¹⁶⁹ Pasteurization of donor milk does affect some nutritional and immunologic components, but many immunoglobulins, enzymes, hormones, and growth factors are unchanged or minimally decreased. Finally, symptoms of feeding intolerance, more commonly seen with formula-feeding, include vomiting, water-loss stools, increased abdominal girth, and increased gastric residuals.¹⁶⁹

Inadequate nutrient intake is common in premature infants for a variety of reasons including an underdeveloped suck reflex, need for tube feeds, and, the variability in nutrient contents of the milk. Feeding difficulties can occur twice as commonly in premature compared to term infants.¹⁷¹ Premature infants less than 28 weeks have significant difficulties with initiation and progression to maximal gavage and oral feedings. Typically, healthy premature infants achieve full oral feeding skills by 36 to 38 weeks.¹⁷² Nonnutritive sucking has been shown in premature infants to decrease in length of stay, improved transition from tube to bottle feeds, and better bottle feeding performance and behavior.¹⁷³ Continuous tube-feeding reduces fat delivery to the infant when compared with intermittent bolus feeding.¹⁷⁴ Differences in nutrient contents occur with milk and donor milk due to variable “milk collection and storage, the feeding of ‘spot’ samples (individual samples of expressed milk from one or both breasts, or milk partially expressed from one breast), and the use of feeding tubes.”¹⁶⁷ Furthermore, the milk is often refrigerated and/or frozen. Finally, there is a significant decline in protein from transitional to mature milk, and the concentrations of protein and sodium decline through lactation; therefore, supplementation is often recommended in the premature infant.

Intolerance of feeds in neonates could be secondary to anatomic variations including obstruction (such as congenital or acquired atresia) and dysmotility. Anatomic causes should be ruled out with imaging studies (x-rays, followed by contrast studies). In neonates, ultrasound may be useful to identify external obstructions such as enteric duplication cyst or mesenteric cyst. Bilious emesis in neonates requires an immediate evaluation for malrotation and midgut volvulus. The use of ranitidine in neonates is controversial and not recommended in premature infants due to its association with increasing incidence of NEC.¹⁷⁵

In neonates that cannot tolerate enteral feeds due to immaturity, congenital anomalies, or hemodynamic instability, or enteral feeds do not meet caloric needs, the use of parental nutrition is essential. As neonates and infants have limited reserves, the use of total parenteral nutrition (TPN) should be fairly liberal. Premature infants may show signs of starvation in 1 to 2 days and young infants require TPN if starvation extends 4 to 5 days, below the 7- to 10-day threshold used in adults. Furthermore, the return of bowel function after surgery may be delayed in premature infants, and many neonates on TPN have never been on full enteral feeds, encouraging the early use of TPN.

Neonates are usually maintained on a high dextrose solution for the first 2 days of life, unless a prolonged starvation is anticipated. Dextrose concentrations in the TPN are generally started at 10% to 12.5%, as larger amounts are associated with hyperglycemia. The concentration is slowly increased to 20% to 25%, monitoring the levels along with electrolytes regularly. The risk of developing phlebitis in peripheral veins increases when the osmolarity exceeds 600 to 900 mOsm/L,¹⁷⁶ translating to approximately 12.5% dextrose. Isotonic lipid infusions are also commonly coin fused with TPN protecting the peripheral veins. Finally, cycling TPN under 24 hours usually requires the child to be approximately 5 kg and to tolerate longer periods off TPN without development of hypoglycemia.

When ordering TPN, we start by calculating the total fluid and caloric needs of the child. We generally order the lipids in quantities of g/kg/d, starting at 0.5 to 1, advancing to 3 by 0.5 to 1 each day. Lipids will provide approximately 35% to 40% of the calories at goal. Protein is ordered next starting at 0.5 to 1 g/kg/d, advancing by 0.5 to 1 each day, to a goal of 2.5 to 3 g/kg/d for a newborn as stated above. Proteins should provide approximately 15% to 20% of the calories. Carbohydrates are calculated to provide 45% to 50% of the calories, starting at 4 to 6 mg/kg/min and advancing by 1 to 2 to a goal of 12 mg/kg/min. The dextrose% multiplied by the total volume over a day (rate per hour multiplied by 24 hours), times a constant 0.69, divided by the weight provides the mg/kg/min. Additives to TPN are standard with vitamins, minerals, and trace elements. The electrolytes are ordered based on laboratory values and the additives are adjusted for long term using laboratory values. Generally, we monitor the chloride-acetate ratio based on the acid-base status and our goals for a given patient, promoting the acetate to buffer a respiratory acidosis. Finally, the calcium-phosphate ratio is adjusted to provide the maximum amounts without causing formation of a precipitate. As the

calculations can quickly become complex, we recommend employing a dietician or pharmacist familiar with neonatal TPN at institutions that commonly encounter the need to order long-term TPN in neonates.

Complications of TPN are categorized into metabolic, hepatobiliary, mechanical, and infectious. Metabolic complications include hyper- and hypoglycemia, metabolic derangements such as acid–base disturbances, electrolyte abnormalities, and metabolic bone disease. Hyperglycemia is secondary to excessive dextrose infused or rapid increase in the concentration. Hyperglycemia can result in osmotic diuresis, dehydration, electrolyte abnormalities, impaired phagocytosis, and liver steatosis.^{177,178} Therapy for hyperglycemia includes lowering the rate of infusion, despite the loss in calories. If hyperglycemia continues, an insulin drip, separated from the TPN due an unpredictable response to insulin by neonates, can be started. Hypoglycemia occurs with a sudden drop in the rate of glucose provided. As mentioned above, cycling is not safe in this age group, and discontinuation of TPN should be done only after decreasing the rate over 1 to 2 hours. Metabolic acidosis from excess chloride or cysteine hydrochloride can cause acidosis; whereas excess acetate can cause alkalosis. Electrolyte abnormalities can occur with any of the following: sodium, potassium, magnesium, phosphate, and calcium.

Metabolic bone disease, which occasionally presents as a pathologic fracture, includes osteopenia, osteomalacia, and rickets. Calcium and phosphorus efficiency, excessive urinary losses of calcium secondary to diuretics, and excessive vitamin D intake, and aluminum toxicity can all contribute to metabolic bone disease. Maximizing calcium and phosphorus intake, and withdrawing vitamin D from these patients actually improves bone demineralization, resolution of bone pain, positive calcium balance, and normalizes active vitamin D and parathyroid hormone levels.

Hepatobiliary complications include cholestasis, steatosis, and cholelithiasis. Prematurity, prolonged TPN use, and sepsis can contribute to these complications. Cholestasis is the most common and occurs 2 to 3 weeks after initiation. Prevention strategies for cholestasis include enteral feeding, weaning from TPN, and prompt treatment of sepsis. Use of antibiotics to decrease bacterial overgrowth and translocation has been successful but measures to promote bile flow have not shown to decrease cholestasis. Use of omegaven and decreasing the lipid component of TPN has shown decreased rates of cholestasis.

Mechanical complications of TPN arise from the need for venous access. Cardiac arrhythmias, thrombosis, and infection can occur secondary to central line use. Proper positioning can avoid the rate of cardiac irritation by the catheter tip. Thrombosis can be prevented and treated with the use of prophylactic and therapeutic doses of anticoagulation. Prolonged thrombosis is a risk for line infection. Furthermore, many patients on chronic TPN lose central access secondary to chronic thrombosis. Finally, infectious complications can occur with and without a central line. Central lines require meticulous care during insertion and maintenance.¹⁷⁹ Fever, a sudden rise in bilirubin, and glucose intolerance are indicators of sepsis. Sepsis can occur while on TPN from microorganisms that enter the blood stream via the catheter, via infusion solutions, and from translocation from a disused, atrophic GI tract. Finally, antibiotic-coated catheters and ethanol locks have been shown to decrease rates of line infection.

Hypoglycemia

The fetal liver contains the enzymes needed for gluconeogenesis and glycogen synthesis but only glycogen synthesis occurs in utero. Glycogen deposition increases from 3.4 mg/g of liver tissue at 8 weeks gestation to 50 mg/g by term.¹⁸⁰ At birth, the glucose levels in the term neonate fall rapidly for the first hour from 80% to 90% of maternal levels, then rises and stabilizes by hour 3 after birth, independent of enteral intake.¹⁸⁰ Within 12 hours, hepatic glycogen stores reach 10% of their initial levels.¹⁸⁰ In fact, hypoglycemia in breast-fed term neonates is uncommon, with glucose production increasing to 4 to 6 mg/kg/min in the first few days, with glycogenolysis providing a third of the glucose production.¹⁸⁰ Preterm neonates, however, have increased rates of hypoglycemia because they have lower hepatic glycogen reserves, decreased activity of gluconeogenic enzymes, and a reduced ketogenic response.¹⁸⁰

Following delivery and clamping of the umbilical cord, the newborn's supply of glucose is abruptly stopped. Over the next several hours, the neonate is susceptible to hypoglycemia, as defined as a serum glucose level below 47 mg/dL (2.6 mmol/L).¹⁸¹ In order to prevent this hypoglycemia, the neonate relies on a steady supply of substrate, such as breastmilk, with an inability to use the relatively small amount of stored glycogen. The major energy source changes from glucose to fat during this adaptive

phase. Infants born small for gestational age (<2 kg or below the 10th percentile), large for gestational age (>4 kg or above 90th percentile), intrauterine growth restriction, those with insulin-dependent mothers, or prematurely (<37 weeks) are at higher risk for hypoglycemia.¹⁸²

Symptoms of hypoglycemia may include jitteriness, tachypnea, hypotonia, poor feeding, apnea, temperature instability, seizures, and lethargy.¹⁸³ Unfortunately, the infant may also remain asymptotic with severe hypoglycemia, highlighting the importance of screening in high-risk infants in the first hour of life. Treatment varies from observation, initiation of feeding, giving dextrose (D10 2 mg/kg bolus followed by 80 mL/kg/d) via IV, starting TPN with a glucose infusion rate (GIR) of 4 to 6 mg/kg/min at 80 mL/kg/d with steady increase in GIR based on glucose levels to target a level above 40 mg/dL.

Bilirubin Metabolism

One of the unique aspects of neonates is the extremely common, self-limited rise in bilirubin levels in the first few weeks after birth. The liver metabolizes albumin-bound bilirubin, created in the breakdown of hemoglobin, by conjugation using uridine diphosphate glucuronyl transferase (UDPGT). In term neonates, hepatic UDPGT is only expressed at about 1% of the adult levels.¹⁸⁰ Once hydrophilic conjugated bilirubin is excreted into small intestines, however, increased reabsorption into the blood as part of the enterohepatic circulation can also occur. The rise in bilirubin is at an earlier onset, for a longer duration, at a greater frequency, and severity in preterm neonates due to higher production from the larger proportion of senescent red blood cells, reduced ability to uptake bilirubin, and even more reduced UDPGT activity.¹⁸⁰

Hyperbilirubinemia (>5 mg/dL) occurs in 60% of term and 80% of preterm infants during the first week of life.¹⁸⁴ It is one of the most common reasons for hospital readmission for the newborn as the peak level occurs after 3 to 5 days of life, commonly after discharge from the hospital. Etiology can be due to prematurity, increased production, genetic disorder such as Gilbert syndrome, or poorly feeding or exclusively breast-fed late preterm infant.

Jaundice, seen initially in the mucous membranes of the inner mouth or eyes, must be categorized as physiologic or pathologic (occurring in the first 24 hours secondary to hemolysis or elevated levels for expected postnatal age and birth weight). Bilirubin toxicity starts with initial phase of sleepiness, hypotonia, poor feeding, and progresses to lethargy and irritability, and finally seizures or a coma.¹⁸⁵ Bilirubin-induced neurologic dysfunction (BIND) is tracked by following mental status, tone, and the infant's cry. Continued unrecognized bilirubin elevation can eventually lead to seizures, developmental delay, hearing deficits, oculomotor disturbances, and kernicterus (permanent brain injury). There is no cure for kernicterus.¹⁸⁶

Management of elevated bilirubin is guided by established nomograms. Phototherapy promotes photochemical reactions that change the shape and structure of the bilirubin: photo-isomerization converts bilirubin to water-soluble isomers that are excreted in the bile; photo-oxidation converts bilirubin to water-soluble products excreted in the urine. Fractionated bilirubin levels should be closely followed as the direct component can increase with phototherapy leading to a "bronze baby." Hydration should also be carefully monitored as the therapy can increase insensible losses. Ensuring skin integrity, thermoregulation, and monitoring stool patterns should also be part of the management. In patients with Rh or ABO incompatibility, the use of intravenous immunoglobulin may reduce the need for the next level of therapy, exchange transfusion.¹⁸⁷

Exchange transfusion is similarly guided by levels on nomograms. The infant is made NPO, and requires IV access (usually umbilical access), and correction of hypoglycemia, hypocalcemia, hypotension, hypothermia, and acidosis. Thromboembolic complications, cardiac arrhythmias, sepsis, and NEC can also occur. During exchange, phototherapy should still be continued and bilirubin levels should continue to be monitored.

CONCLUSION

A thorough understanding of fetal, neonatal, and pediatric physiology is essential for understanding and treating fetal and pediatric surgical problems. Pediatric patients are not "tiny adults" and the medical and surgical approaches must be grounded in the understanding of their physiology and pathophysiology. Finally, we believe that complex fetal and neonatal surgery should be performed in centers with robust experience, which have pediatric subspecialists and facilities to care for these patients. Already, establishment of levels of care is underway to categorize various pediatric surgical institutions.¹⁸⁸ This should globally improve outcomes on all pediatric patients by creating overall

expertise in institutions, which plays a significant role in pediatric surgical outcomes.

Chapter 100

Fetal Intervention

George B. Mychaliska and Darrell L. Cass

Key Points

- 1 Four fetal conditions clearly benefit from fetal intervention: congenital cystic adenomatoid malformation (CCAM), fetal sacrococcygeal teratoma (SCT), a fetus with airway obstruction from a giant neck mass or laryngeal atresia, and twin-to-twin transfusion syndrome (TTTS).
 - 2 Any fetal therapy requires (a) accurate diagnosis of the condition and any associated anomalies that may have an impact on outcome, (b) reliable prediction of which individual fetuses will die or suffer serious long-term morbidity without fetal intervention, and (c) that the procedure improves the outcome of the fetus with little to no maternal risk.
 - 3 Preterm labor is the single biggest concern during the operation and in the postoperative period.
 - 4 For a fetus with a lung mass, the only indication for fetal intervention is the presence of hydrops.
 - 5 For a fetus with sacrococcygeal teratoma, increased aortic velocity, increased combined cardiac output, increased cardiac-to-thoracic ratio, a dilated inferior vena cava, or reversed end-diastolic umbilical blood flow are sensitive early predictors of impending hydrops and fetal demise; before 28 weeks' gestation, open fetal surgery and resection is the treatment of choice.
 - 6 Fetal intervention may play a role in the management of a small cohort of fetuses with the most severe form of congenital diaphragmatic hernia (CDH).
 - 7 An ex utero intrapartum treatment (EXIT) procedure is the treatment of choice for fetuses with a giant neck mass or congenital high airway obstruction syndrome (CHAOS).
-

Fetal surgery has emerged as an independent subspecialty at the intersection of pediatric surgery and maternal–fetal medicine. It is a field that has arisen from clinical necessity. Pediatric surgeons, maternal–fetal medicine specialists, and neonatologists became frustrated with the management of a number of congenital structural anomalies in which the baby died or suffered severe lifelong disability despite all efforts at postnatal treatment. With the advent of prenatal ultrasound in the 1970s, many conditions were diagnosed before birth. Fetuses were followed, and the prenatal natural history was elucidated. It became clear that a component of organ failure was acquired because of ongoing alterations in fetal development caused by the anomaly. Thus, it made sense that fetal interventions may be of benefit to correct the pathophysiology and restore normal fetal development in the hope of improving survival and decreasing morbidity.

1 The first successful fetal intervention was reported by Sir A. W. Liley, who successfully transfused a hydropic fetus for Rh disease.¹ Although a few attempts were made at exchange transfusion by an open technique in the 1960s, modern fetal surgery was envisioned and developed by Dr. Michael Harrison at the University of California, San Francisco (UCSF) in the late 1970s.² It was at UCSF that the concept of a fetal treatment program was developed, permitting a true multidisciplinary approach to fetal diagnosis and treatment. The first open fetal operation was performed in 1982, at which bilateral ureterostomies were performed in a 21-week-gestation fetus with obstructive uropathy.³ In the intervening years, tremendous progress has been made in the development of fetal surgery techniques, including advances in maternal–fetal anesthesia, tocolysis (prevention of preterm labor), and the development of less invasive surgical techniques. During this same period, there have been significant advances in neonatal surgical critical care that has improved the outcome of fetuses with congenital anomalies. Thus, fetal surgery indications must be continually reassessed in the context of emerging prenatal and postnatal therapies. At the present time, there are only three fetal conditions that show clear benefit from fetal surgery during pregnancy: congenital cystic adenomatoid malformation (CCAM), fetal SCT, and twin-to-twin transfusion syndrome (TTTS). Open fetal surgery at the end of pregnancy, the ex utero intrapartum treatment (EXIT) procedure, has proven effective for the treatment of giant neck masses and laryngeal atresia. The EXIT procedure has been expanded to treat conditions

that result in impending respiratory failure at birth using the EXIT-ECMO (extracorporeal membrane oxygenation) strategy, but the efficacy of this technique is still unproven. Fetal interventions, including open, fetoscopic, and percutaneous, have been used to treat a number of other fetal disorders, such as congenital diaphragmatic hernia (CDH), myelomeningocele (MMC), urologic obstruction, chylothorax, and, most recently, congenital heart malformations. Many of these procedures are promising, but questions remain regarding the natural history of these disorders, selection criteria, and efficacy.

FETAL IMAGING AND PRENATAL DIAGNOSIS

2 Fetal imaging is a critical component of the decision-making process in fetal surgery. Criteria that must be met to consider fetal surgery include (a) accurate diagnosis of the condition and any associated anomalies that may have an impact on outcome, (b) reliable prediction of which individual fetuses will die or suffer serious long-term morbidity without fetal intervention, and (c) demonstration of improved fetal outcome with minimal maternal risk.

Most congenital defects can now be detected before birth with the use of high-resolution ultrasound, color Doppler, and fetal magnetic resonance imaging (MRI). Frequently diagnosed anomalies include diaphragmatic hernia (Fig. 100-1), congenital lung lesions (Fig. 100-2), obstructive uropathy, neural tube defects, neck masses (Fig. 100-3), congenital heart defects, and SCT. Other surgical disorders include abdominal wall defects (gastroschisis and omphalocele), intestinal atresias, and cystic and solid abdominal masses. Although ultrasound is the predominant prenatal screening and diagnostic modality, fetal MRI has proven particularly helpful in the further evaluation of central nervous system, chest, and neck anomalies.⁴⁻⁶ Fetal echocardiography is essential in the evaluation of congenital heart disease and is also useful in evaluating abnormal cardiac function associated with other birth defects.⁷⁻⁹

Prenatal detection and serial ultrasonographic evaluation of these disorders have enhanced our understanding of their natural history, and have significantly improved perinatal management. Pediatric surgeons familiar with the management of congenital malformations before and after birth, along with obstetricians, neonatologists, geneticists, and other specialists, participate in family counseling and together contribute to optimal maternal-fetal management. Such multidisciplinary teams may recommend that the timing, mode (cesarean vs. vaginal delivery), or location of delivery be altered. Furthermore, in rare circumstances prenatal diagnosis permits in utero treatment of the developing fetus to prevent, reverse, or minimize fetal organ injury or death. In one study, prenatal consultation led to a change in pregnancy management in 67% of 221 pregnancies, of which 11 patients (5% of total) benefited from fetal intervention.¹⁰

Although most congenital anomalies are best managed with the use of appropriate medical and surgical therapy after delivery at term, rare fetal anomalies may benefit from surgery before birth. The innovations required for fetal surgery include the development of new surgical, anesthetic, and tocolytic techniques, as well as the resolution of such ethical issues as maternal safety and future maternal reproductive potential.¹¹⁻¹³

Figure 100-1. Coronal section of fetal magnetic resonance image (MRI) of a 30-week fetus with left congenital diaphragmatic hernia (CDH). The stomach (*small arrow*) and intestines are herniated into the left chest. The left lung is severely hypoplastic (*large arrow*).

Figure 100-2. Coronal section of a fetal magnetic resonance image (MRI) of a 24-week fetus with a large left lung mass (bronchopulmonary sequestration). The left diaphragm is flattened and there is moderate dextroposition of the heart. A large vessel is seen coming from the low thoracic aorta (*arrow*). The congenital cystic adenomatoid malformation volume ratio (CVR) was 1.96; however, hydrops did not develop and the baby “grew around” the mass.

Figure 100-3. Coronal section of a fetal magnetic resonance image (MRI) of a 31-week fetus with a large left neck lymphatic malformation. The mass extends to the apex of the left chest (*arrow*). There is moderate left-to-right tracheal deviation. This fetus was delivered with an ex utero intrapartum treatment (EXIT) procedure.

MATERNAL–FETAL RISKS

Fetal surgery is unlike all other surgical specialties in that it involves two patients; the surgeon must operate on a healthy maternal patient to fix a disease in the affected fetus. This paradigm presents

challenging moral and ethical conflicts that must be considered and balanced in each circumstance. Chervenak and McCullough¹⁴ and others have helped to provide an ethical framework within which fetal surgery should exist. The keys to this framework are that (a) the fetal operation has significant chance of being lifesaving or of preventing serious or irreversible disease in the fetus; (b) the procedure involves low mortality and morbidity risk to the fetus; and (c) the operation has very low mortality and morbidity risk to the pregnant woman, including risks to future pregnancies. In light of these considerations, a number of contraindications to fetal intervention exist, including chromosomal abnormalities, the presence of other major anomalies, and significant maternal comorbidities.

There are significant maternal and fetal risks associated with fetal surgery that must be weighed for each patient. For the fetus, there is risk of preterm delivery, fetal death, or survival with poor outcome. Most indications for fetal surgery, however, are ones in which the fetus would die without it, and therefore the risk-to-benefit ratio is very favorable. For those interventions aimed at improving the outcome of fetuses with nonlethal conditions, the risk–benefit ratio is much more difficult to assess.

The risks and benefits to the mother depend on the invasiveness of the fetal surgical operation. In any intervention, benefits to the mother include the psychological reward from doing everything possible to improve the condition of the unborn baby. In selected cases, there is physiologic benefit in preventing the possibility of “mirror syndrome,” a preeclampsia like condition in which the mother’s condition “mirrors” that of a sick or dying fetus.¹⁵ In the presence of this syndrome, fetal surgery is contraindicated and urgent fetal delivery is important to ensure maternal health. For the mother, fetal surgery adds the discomfort of one or two operations that would not have been required otherwise. For mothers who have hysterotomy other than low transverse, and for all mothers having open fetal surgery, there are theoretical risks to subsequent pregnancies and future fertility. When maternal fertility following fetal surgery was studied, however, it was found that 32 of 35 mothers were able to achieve successful subsequent pregnancies and 31 live births resulted.¹¹ Furthermore, if a classic cesarean section is performed during open fetal surgery, subsequent deliveries must be performed by cesarean section. Specific complications resulting from a classic cesarean section in subsequent pregnancies include uterine dehiscence and uterine rupture.¹⁶ Postoperatively, nonhydrostatic pulmonary edema may occur in the mother. This problem was more prevalent in the early experience of open fetal surgery, but it still persists. In a trial reported by Harrison et al.¹⁷ 3 of 11 mothers developed pulmonary edema and required oxygen after fetal surgery. In each of these patients the symptoms were mild and resolved within 48 hours. The cause of this phenomenon remains unclear, but is likely related to uterine manipulation and the release of prostaglandins or thromboplastins that alter maternal lung vascular permeability.¹⁸ As with all obstetric surgery, blood loss may be significant and mothers undergoing fetal surgery occasionally require blood transfusion.¹⁹ Chorioamniotic membrane separation and preterm labor remain the Achilles’ heel of fetal interventions.^{20,21} Surgical approaches that involve a smaller hysterotomy and more minimally invasive techniques appear to lower these risks.²² Specifically, fetoscopic and percutaneous approaches lessen the maternal and fetal risks.²³ These techniques allow vaginal delivery after fetal surgery and appear to decrease the incidence of preterm delivery.²⁴ Thus far, no maternal deaths have occurred at the major fetal surgery centers in the United States and Europe.

SURGICAL TECHNIQUES: OPEN, FETOSCOPIC, AND PERCUTANEOUS APPROACHES

Numerous technical aspects of fetal surgical procedures have evolved over 30 years of experimental and clinical work and have been reviewed in detail elsewhere.^{25–28} The comprehensive care of the fetal surgery patient is labor intensive and requires multidisciplinary cooperation between all team members. In the operating room, the leader of the fetal surgery team is either a pediatric surgeon or maternal–fetal medicine specialist with specific training in fetal surgical techniques. The leader should be chosen depending on the procedure and specific expertise.²⁹ Responsibility for the patient’s anesthesia is shared between an obstetric anesthesiologist for the mother and a pediatric anesthesiologist for the fetus. Both anesthesiologists should have special expertise in maternal–fetal anesthesia and work together as a team. A high-resolution ultrasound machine with color and enhanced Doppler is essential and used throughout the procedure to assess fetal and placental position; monitor fetal heart rate, cardiac function, and volume status; and assess amniotic fluid levels.³⁰ A pulse oximetry probe is placed on the fetal hand to assess fetal oxygen saturation and continuous heart rate. A peripheral intravenous catheter

is often placed in the fetus for fluid, blood, and medication delivery. A surgical nursing team trained in the specific aspects of fetal surgical procedures and instrumentation is mandatory.

Open fetal surgery is performed with general and epidural anesthesia. Epidural delivery of a fentanyl/bupivacaine mixture provides optimal postoperative analgesia and minimizes uterine irritability. Intraoperatively, inhaled isoflurane titrated to an end-tidal concentration of 2% or higher is used to achieve uterine relaxation, which is critical to successful outcomes. Because of the risk of postoperative pulmonary edema, the mothers are fluid restricted during these procedures and receive as little as 500 mL of crystalloid. The patient is positioned supine with a roll under the right side to avoid compression of the inferior vena cava by the gravid uterus. The uterus is exposed through a low transverse abdominal incision. If the placenta is positioned posteriorly, subcutaneous flaps and a midline incision from the umbilicus to the pubis permit adequate uterine exposure. In cases of an anterior placenta, the fascia and rectus muscles are divided transversely so that the uterus can be tilted forward for a posterior hysterotomy. A large abdominal ring retractor is useful for abdominal wall retraction. After uterine relaxation is confirmed by palpation, the orientation of the fetus and placenta is confirmed by ultrasound. For open fetal surgery during pregnancy, a classical cesarean section incision is made. For the EXIT procedure, it is preferable to perform a low transverse hysterotomy. Two opposing traction sutures are placed with ultrasound guidance to provide hemostasis and to secure the fetal membranes to the uterine wall. The myometrium is then incised, and a hemostatic uterine stapler is used to open the uterine wall in both directions. A rubber catheter connected to a rapid infuser is inserted into the amniotic space to replace egress of amniotic fluid with warmed Ringer lactate. Infusion of warmed fluids is critical to maintain fetal temperature and amniotic volume and to minimize the risk of uterine contractions and umbilical cord compression (Fig. 100-4).

One of the unique requirements of fetal surgery is that the surgeon must operate on the fetus and then return the fetus to the amniotic environment in such a way as to minimize disturbance to the continuing pregnancy. The uterine closure must have adequate strength to prevent rupture, must have membrane reapproximation to prevent amniotic fluid leakage, and must limit risks for preterm labor or future infertility. Currently, the uterus is closed in two layers using an outer layer of full-thickness 0 polydioxanone (PDS) retention sutures and an inner running layer of 2-0 PDS to close the myometrium and membranes. Before the closure is complete, the rapid infuser is used to restore amniotic volume and administer antibiotics. An omental pedicle is secured over the hysterotomy to seal any small leaks from the full-thickness sutures.

Figure 100-4. Fetal surgery of a hydropic 24-week fetus with a large left lung mass. **A:** Intraoperative ultrasound to locate the placenta and fetus. **B:** Uterine stay sutures are elevated to facilitate the use of the uterine stapler. **C:** The mass has been removed and the remaining normal left lung is evident. A bolus of crystalloid is given into the umbilical vein, and the chest is being closed.

3 Preterm labor is the single biggest concern during the operation and in the postoperative period. The mother receives a 50-mg indomethacin suppository 4 hours before surgery, and remains on indomethacin for 48 hours postoperatively. Daily echocardiography is essential; if there is evidence of patent duct arteriosus (PDA) restriction, then the indomethacin is stopped. During the operation terbutaline or nitroglycerin infusion can be used to help control uterine irritability and enhance relaxation. During closure of the hysterotomy, the mother is given a 6-g bolus dose of magnesium sulfate followed by a continuous infusion of 2 to 4 g/h. Postoperatively the mother is observed in an intensive care unit (ICU) setting for close monitoring for pulmonary edema, fluid management, and uterine irritability. The magnesium sulfate is continued for 48 to 72 hours with close monitoring of magnesium levels and signs of toxicity. On the second to third postoperative day, usually the magnesium and indomethacin can be weaned, and the patient is converted to subcutaneous terbutaline or oral nifedipine. The patient is maintained on bed rest until the time of delivery. Postoperatively, daily ultrasound examinations help to assess the ductus arteriosus, amniotic fluid index (estimate of fetal urine output or of amniotic fluid leak), and fetal movement (marker of fetal well-being).

Fetoscopic surgery has been used most recently to permit a number of fetal surgical interventions, such as tracheal occlusion, laser ablation of communicating vessels in TTTS, and fetoscopic ablation of posterior urethral valves for fetuses with obstructive uropathy. Initially, these procedures were performed by exposing the uterus through a maternal laparotomy. More recently, surgeons have placed trocars percutaneously into the uterus through the intact maternal abdominal wall. Specially designed fetoscopic instruments have been developed that have allowed for single-port procedures.³¹ Visualization during fetoscopy requires continuous irrigation through the fetoscope. This permits maintenance of uterine fluid volume, avoids risk of air embolus with gas distention of the uterus, ensures a continuously washed operative field, improves visibility by exchanging the cloudy amniotic fluid with lactated Ringer solution, and keeps the fetus warm.

RATIONALE AND OUTCOME OF FETAL SURGERY FOR SPECIFIC CONGENITAL ANOMALIES

Lung Malformations

CCAM and bronchopulmonary sequestration are the most common congenital lung malformations, and the most common fetal thoracic lesions that may benefit from fetal intervention.³² The incidence of these lesions has been estimated at 1 in 25,000 to 35,000 pregnancies;³³ however, current referral patterns to fetal therapy centers suggest they may occur more frequently. Grossly, a CCAM is a discrete, space-occupying intrapulmonary mass that contains variable-sized cysts. These lesions do not function in normal gas exchange; however, airspaces within these masses communicate with the tracheobronchial tree. Histologically, CCAM is distinguished from other lesions and normal lung by (a) polypoid projections of the mucosa, (b) an increase in smooth muscle and elastic tissue within cyst walls, (c) an absence of cartilage (except that found in “entrapped” normal bronchi), (d) the presence of mucus-secreting cells, and (e) the absence of inflammation. In contrast, bronchopulmonary sequestrations (BPSs) (intralobar or extralobar) are masses of nonfunctioning lung tissue that are supplied by an anomalous systemic artery and do not have connection to the native tracheobronchial tree. The pathogenesis of both lesions is unknown, but they are thought to arise during the fifth to sixth week in embryonic development, and may result from abnormalities in growth signals between the branching airway epithelium and pulmonary mesenchyme.^{34,35} Congenital lung lesions are commonly diagnosed by prenatal ultrasound as an echogenic solid, or cystic and solid thoracic mass. Not infrequently, these lesions may be seen to have a systemic blood supply on Doppler ultrasound. Although CCAM and BPS have been distinguished prenatally in the past by the presence or absence of a systemic vessel, it is now recognized that these lung lesions represent a continuum of pulmonary maldevelopment and there are lesions that have clinicopathologic features of both.^{36,37} Fetal MRI may enhance diagnostic accuracy in examining these lesions and distinguishing them from other thoracic abnormalities, such as congenital lobar emphysema, bronchial atresia, bronchogenic cyst, and congenital diaphragmatic hernia (CDH).^{38,39}

The natural history and clinical spectrum of these anomalies are variable, but they appear to depend mostly on the size of the mass and the secondary physiologic derangement. The growth of CCAMs usually plateaus between 25 and 28 weeks, at which time the fetus appears to grow around the lesion. The vast majority of small to moderate-sized CCAMs remain asymptomatic during fetal life. Approximately 15% of CCAMs will shrink significantly before birth.⁴⁰ In contrast, large lesions represent 5% to 10% of CCAMs and may produce significant mass effect, which can lead to pulmonary hypoplasia, impaired fetal swallowing and polyhydramnios, and impaired venous return and heart failure. Congestive heart failure in the fetus, known as nonimmune fetal hydrops, is defined by the presence of skin or scalp edema, or by fluid accumulation in one or more serous cavities (ascites or pericardial or pleural effusions). The risk of hydrops appears to depend on the size and rate of growth of the mass, and results from compression of the superior vena cava and impaired venous return.⁴¹ It has been demonstrated that hydrops is a harbinger of fetal demise, and is associated with near 100% mortality.⁴² Rarely, hydrops is due to a tension hydrothorax from extralobar sequestration.⁴² As a prognostic factor, the CCAM volume ratio (CVR) has been developed to correlate the relative size of these lesions with fetal and postnatal outcome.⁴³ In one series in which 58 fetuses with a lung mass were followed prospectively, 75% of fetuses (12 of 16) with a CVR greater than 1.6 developed hydrops, whereas only 17% (7 of 42) with a CVR of 1.6 or less had this complication. However, the CVR was not predictive of hydrops if a CCAM had a dominant cyst, which may enlarge at an unpredictable rate.

4 For a fetus with a lung mass, the only indication for fetal intervention is the presence of hydrops. Most commonly, hydrops occurs in the period of rapid growth of these lesions between 19 and 26 weeks' gestation.^{32,42,43} Fetuses with a lung mass should be followed closely. It is recommended that those with a CVR less than 1.6 receive weekly ultrasound up to about 28 weeks' gestation, whereas those with a CVR greater than 1.6 should be examined as frequently as two to three times per week. If signs of hydrops appear, the treatment options include percutaneous placement of a thoracoamniotic shunt for lesions with a dominant cyst, and open fetal thoracotomy and mass resection for more solid lesions. Use of the laser or radiofrequency ablation to debulk a large CCAM cannot be recommended now because of technical limitations and inability to control energy distribution and postprocedure swelling.^{44,45}

Fetal surgery for fetal lung masses requires open hysterotomy (Fig. 100-4). Intraoperative echocardiography is critical to assess fetal intravascular volume and right ventricle filling. These fetuses have tamponade physiology and generally benefit from a fluid bolus before thoracotomy. A relatively large thoracotomy is required to permit adequate exposure, and the mass is delivered slowly to prevent rapid decreased cardiac venous return. At resection, the presence of a systemic vessel must be considered.

The first successful open fetal surgery for CCAM was reported in 1990 by Harrison et al. at UCSF.⁴⁶ Since then, there have been reports of 22 open fetal resections of lung masses, with 50% survival.³² Delays in referral and intervention, the presence of maternal "mirror" syndrome, preterm labor, chorioamnionitis, and technical difficulties associated with the procedure have limited outcomes in half of the cases. Recent evidence suggests that administration of maternal steroids may reverse the pathophysiology of hydrops, but this strategy requires further validation.^{47,48}

Sacroccygeal Teratoma

Sacroccygeal teratoma (SCT) is the most common neonatal tumor, with an incidence of 1 in 35,000 live births.^{49,50} Thought to arise from totipotent somatic cells originating in the caudal cell mass, this tumor contains multiple neoplastic tissues that lack organ specificity, are foreign to the sacroccygeal region, and are derived from all three germ layers. The postnatal mortality of SCT is low, despite that about 10% of neonatal lesions are malignant. However, the prenatal mortality from SCT is greater than 50%. The causes of death in fetal SCT are multifactorial, but primarily involve dystocia with tumor rupture and bleeding at the time of delivery, or high-output cardiac failure and hydrops from high blood flow within the mass.⁵¹ The evolution of high-output cardiac failure before the development of placentomegaly and hydrops in a fetus with SCT is the sole indication for fetal surgical intervention. Furthermore, SCT may lead to maternal mirror syndrome (Ballantine syndrome).⁵² In this condition, the mother experiences progressive preeclampsia like symptoms, including vomiting, hypertension, peripheral edema, proteinuria, and pulmonary edema, caused by the release of placental vasoactive factors or endothelial cell toxins from the edematous placenta. This syndrome is reversed only by delivering the child and the placenta, but not by removing the SCT prenatally.

5 The diagnosis of SCT can be made by fetal ultrasound as early as 14 weeks' gestation.⁵³ The

sonographic appearance may be cystic, solid, or mixed, and may demonstrate irregular echogenic patterns secondary to areas of tumor necrosis, cystic degeneration, internal hemorrhage, or calcification. Ultrasound is important to assess abdominal or pelvic extension, evidence of bowel or urinary tract obstruction, and the integrity of the fetal spine, and to document lower extremity function. Fetal MRI is helpful to delineate the anatomy and may be useful to distinguish these lesions from MMC, meconium pseudocyst, and obstructive uropathy. Fetal echocardiography and Doppler ultrasound measurements are important in the diagnostic assessment and follow-up of fetuses with these conditions. Increased aortic velocity, increased combined cardiac output, increased cardiac-to-thoracic ratio, a dilated inferior vena cava, or reversed end-diastolic umbilical blood flow appear to be sensitive early predictors of impending hydrops and fetal demise.^{8,54} For fetuses greater than 28 weeks' gestation, these findings are an indication for emergency cesarean delivery and postnatal resection. For fetuses less than 28 weeks, open fetal surgery and resection is the treatment of choice. Minimally invasive approaches to interrupt the tumor's blood supply with radiofrequency ablation have had limited success⁵⁵ but may be alternatives for a fetus that is a poor candidate for open fetal resection.

Adzick et al.⁵⁶ reported the first successful outcome for fetal surgery resection of a fetus with a large SCT and hydrops in 1997. More recently, investigators from that center have reported 75% survival (three of four) for fetal resection of SCT. A similar high-output heart failure physiology can occur with teratomas in other locations. A fetus with a cervical teratoma and hydrops had successful fetal resection of the lesion at 24 weeks' gestation.⁵⁷

Congenital Diaphragmatic Hernia

At present, the role of fetal intervention in the management of fetuses with congenital diaphragmatic hernia (CDH) is not clear. A hole in the posterolateral diaphragm, left sided in 80% to 85% of cases, permits abdominal viscera to herniate into the chest during fetal development, resulting in pulmonary hypoplasia and pulmonary hypertension. In current practice, more than half of the infants with CDH are diagnosed before birth. At times it can be difficult to distinguish CDH from a cystic lung mass or other cystic lesions. Fetal MRI is useful to enhance diagnostic accuracy, confirm liver position, calculate lung volumes, and further exclude associated anomalies.^{6,58}

Outcome for patients with CDH varies widely, depending on the severity of disease when the disease is diagnosed.⁵⁹ The overall survival of CDH in the United States is 68%.⁶⁰ Although the survival has improved in selected centers,^{61–64} the morbidity of some survivors remains high.⁶⁵ Fetuses with CDH have lower survival rates than those for live-born infants or for infants presenting to a neonatal surgical center. This paradigm has been termed the “hidden mortality” by Harrison et al.⁶⁶ and has been confirmed by multiple investigators.^{67–69} In 2000, Dillon et al.⁷⁰ reviewed the outcomes from a large series of fetuses with CDH registered in the Northern Region Congenital Abnormality Survey in the United Kingdom. Between 1985 and 1997, 201 fetuses were evaluated for diaphragmatic problems, of which 187 had congenital diaphragmatic hernia (CDH) (14 had diaphragm eventration). From this cohort, 38 pregnancies were terminated, 26 of which had “multiple abnormalities,” and 14 pregnancies (7%) were complicated by spontaneous miscarriage or stillbirth. The overall 1-year survival was 37%, but for live-born fetuses the survival was 50%. Furthermore, for those live-born babies with isolated CDH, the overall survival was 59%.

Ultrasound (and more recently MRI) can be used to predict fetal CDH severity. Herniation of the liver into the fetal chest and marked lung hypoplasia as estimated by a lung-to-head ratio (LHR) less than 1.0 are strong predictors of perinatal death.^{71,72} Fetuses without liver herniation through the diaphragm have a reported survival rate between 75% and 93%, whereas those with “liver up” have a survival rate as low as 43%.⁷³ In a report that included evaluation of 174 patients with CDH, an LHR less than 0.9 was associated with only 13% survival, whereas survival was 68% for an LHR 0.9 to 1.2 and 88% for an LHR greater than 1.2.

For selected infants with severe CDH, fetal surgery has been performed in an attempt to reverse the high mortality rate. Initially, complete in utero repair of the diaphragmatic defect was attempted.⁷⁴ This approach, however, led to fetal bradycardia and immediate death after attempts to reduce the liver from the fetal chest resulted in kinking of the ductus venosus.⁷⁵ Subsequently, in utero tracheal occlusion has been used to treat fetuses with severe CDH. It has been shown that temporary tracheal occlusion, performed either as an open procedure or fetoscopically, can prevent the normal egress of lung fluid and enhance growth of the fetal lungs.⁷⁶ In a review of 15 patients treated by open fetal tracheal occlusion at Children's Hospital of Philadelphia (CHOP), survival was 100% for patients with right-sided defects (two of two) and 23% for patients with left-sided defects (3 of 13), compared with

0% survival for a matched group of seven infants with left-sided lesions managed by conventional treatment alone. Endoscopic approaches to fetal tracheal occlusion, termed “fetoscopic” or “FETENDO,” showed more promising outcomes.⁷⁷ However, Harrison et al.¹⁷ from UCSF reported results from a National Institutes of Health (NIH)-sponsored, prospective randomized trial that compared fetoscopic tracheal occlusion with standard postnatal care for fetuses with left-sided CDH, “liver up,” and an LHR less than 1.4. Twenty-four fetuses were randomized, but at this point the trial was stopped because of an unexpected high survival in the standard treatment group and the expectation that fetal therapy in this design would show no benefit. In this study of fetuses with liver-up CDH, the overall 90-day survival rate was 75%, a number much higher than those reported previously. Whereas 8 of 11 (73%) fetuses survived following fetoscopic tracheal occlusion, 10 of 13 (77%) survived with postnatal treatment alone, thus showing no benefit to fetal therapy in this study. As expected, a striking difference in the gestational ages was noted between the two groups. Whereas the standard treatment group delivered at a mean gestation of 37 weeks, the tracheal occlusion group delivered at a mean of 30.8 (range of 28 to 34) weeks’ gestational age. Although fetoscopic tracheal occlusion likely had an effect on lung growth, this response may have been limited by preterm labor, early delivery, and associated lung immaturity. As has been demonstrated in the treatment of other conditions, chorioamniotic membrane separation and preterm labor limit outcomes from fetal surgery.^{20,21} The lack of benefit from fetal therapy may also result from the excellent outcomes that were achieved in the control group. These results certainly suggest that a standardized protocol involving prenatal steroids and expert pre- and postnatal care may improve outcome for fetuses with severe CDH.

Deprest reported results from the use of fetoscopic tracheal occlusion (FETO) in 210 patients. The procedure was performed at a median gestational age of 27 weeks. Although spontaneous preterm prelabor rupture of membranes occurred in 47% of patients, the median gestational age at delivery was 35.3 weeks. The authors estimated that in fetuses with left CDH treated with FETO, the survival rate increased from 24% to 49%.²⁴ The results from this trial are promising but still limited because of a lack of a randomized design and lack of standardized, centralized postnatal care in the control group of fetuses.

6 It is likely that fetal intervention may play a role in the management of a small cohort of fetuses with the most severe form of CDH. Current work is directed at accurate identification of this cohort and optimizing minimally invasive treatment approaches.

Fetal Surgery at the End of Pregnancy

Ex Utero Intrapartum Treatment Procedure

7 As an outgrowth of the fetal intervention efforts, the EXIT procedure was devised to treat fetal airway obstruction caused by large neck masses or intrinsic airway problems.⁷⁸ This approach involves a planned hysterotomy and delivery with preservation of the maternal–fetal placental circulation for oxygenation of the fetus. While on “placental bypass,” up to 2 hours is available for direct laryngoscopy, bronchoscopy, endotracheal intubation, tumor resection, or tracheostomy to secure the airway (Fig. 100-5). The umbilical cord is then divided, and the fetus delivered. Indications for an EXIT procedure include the presence of a large cervical mass with evidence of airway deviation or compression. Polyhydramnios, caused by esophagus compression, is one marker for fetal tracheal compression. Recently, the tracheoesophageal displacement index (TEDI) has been described to assess the degree of tracheal deviation on fetal MRI.⁷⁹ Multiple centers have used the EXIT procedure to stabilize the airway in fetuses with large cervical tumors (e.g., teratomas or lymphatic malformations) with excellent fetal outcomes and very little additional maternal risk (Fig. 100-5).^{80–82}

Figure 100-5. A 36-week fetus with a giant right neck teratoma at ex utero intrapartum treatment (EXIT) procedure. Due to significant tracheal deviation, a tracheostomy was performed on placental support.

An EXIT procedure is the treatment of choice for fetuses with congenital high airway obstruction syndrome (CHAOS). This syndrome is usually caused by laryngeal or tracheal atresia, tracheal stenosis, or a mucosal web. A fetus with this condition develops overdistended, echogenic lungs, which may compress the mediastinum, flatten or evert the diaphragm, and cause hydrops because of compromise of venous return. Fetuses with CHAOS should be delivered with an EXIT procedure to permit tracheostomy and airway control while maintaining the maternal–fetal placental circulation. For fetuses with CHAOS who develop hydrops, early delivery or prenatal tracheostomy are treatment options, depending on gestational age.^{83–85}

EX UTERO INTRAPARTUM TREATMENT–EXTRACORPOREAL MEMBRANE OXYGENATION

The EXIT–ECMO procedure has been developed to treat anticipated respiratory failure at birth. The rationale for this procedure is to transition from a stable intrauterine environment to ECMO while avoiding hypoxemia, barotrauma, hemodynamic instability, and acidosis. This strategy has been applied to severe CDH. Kunisaki et al. reported the largest series of 14 patients who had EXIT–ECMO for treatment of severe CDH.⁸⁶ Inclusion criteria included liver herniation, an LHR less than 1.4, percentage of predicted lung volume by fetal MRI less than 15, and/or congenital heart disease. Overall survival was 64% for this severe subset of CDH patients. Although this therapy is promising, at this time its efficacy is unproven. Variations of this procedure include EXIT-resection for lung lesions,⁸⁷ EXIT–ECMO for fetal thoracic masses,⁸⁸ and EXIT-resection–ECMO for giant chest masses (Fig. 100-6).⁸⁹

Myelomeningocele

MMC was the first nonlethal anomaly to be treated by fetal surgery.^{90–92} MMC, or spina bifida, is a midline defect of the spine and spinal cord that leads to exposure of the contents of the neural canal. It is relatively common, and occurs in 1 of every 2,000 live births. The natural history of fetuses with this condition is variable, but generally mortality is low. Instead, affected newborns suffer lifelong disabilities, which include a combination of paraplegia, abnormalities in bowel or bladder control, sexual dysfunction, skeletal deformations, hydrocephalus, and mental impairment. More than 80% of fetuses with MMC can be identified before birth by maternal serum α -fetoprotein screening. Fetal ultrasound may detect the characteristic spine abnormalities as early as 16 weeks' gestation.

Figure 100-6. A 37-week fetus with severe congenital diaphragmatic hernia (CDH) delivered using the ex utero intrapartum treatment (EXIT)–extracorporeal membrane oxygenation (ECMO) procedure. The airway was secured and ECMO cannulas were placed on placental support.

The rationale for fetal intervention for MMC is based on compelling evidence that associated neurologic deficits do not simply result from incomplete neurulation but rather from chronic mechanical and chemical trauma caused by exposure of the neural tissue to the amniotic environment. Support for this conclusion includes the observation that fetal leg movements decrease with advancing gestational age. Furthermore, in animal models of MMC, in utero repair leads to improved neurologic function and reversal of hindbrain herniation.⁹³

Human fetal interventions for MMC were initially designed to reduce intrauterine exposure of neural elements. Both fetoscopic and open techniques were attempted; however, open methods are considered the current standard. The first successful outcome of fetal surgery repair of MMC was reported by Adzick et al. in 1998.⁹⁰ Since that time multiple centers have reported positive outcomes that suggest that surgical repair of MMC before 25 weeks' gestation can preserve neurologic function, reverse the hindbrain herniation, decrease the incidence of clubfoot, and obviate the need for postnatal placement of a ventriculoperitoneal shunt compared with historical controls.^{91,92,94} No consistent improvement was seen in neurologic or bladder function, however, and these interventions did come at the cost of fetal prematurity (preterm labor) and increased maternal risk. Furthermore, lack of accurate prenatal indicators of neurologic function and absence of matched controls and long-term follow-up hamper evaluation of this approach.

Urinary Obstruction

Obstructive uropathy, one of the most common fetal structural anomalies, occurs in about 1 of 1,000 live births. Of all fetuses with urinary tract dilatation, as many as 90% do not require fetal intervention, such as those with low-pressure dilation, continued good urine output, adequate amniotic fluid volume, unilateral urinary obstruction, or advanced irreversible renal dysplasia.^{95,96} Fetuses with urethral obstruction, severe bilateral hydronephrosis, and preserved renal function may be candidates for fetal intervention. Urethral obstruction, usually caused by posterior urethral valves in a male fetus, leads to decreased fetal urine output, oligohydramnios, and eventually pulmonary hypoplasia, which is often the most important factor affecting postnatal outcome. Fetuses with oligohydramnios present in the early second trimester have mortality rates in excess of 90%.^{97,98}

Prenatal ultrasound is very accurate in the detection of fetal hydronephrosis and in determining the level of urinary obstruction. Because most of the amniotic fluid in middle and late pregnancy is the product of fetal urination, the presence of a normal amniotic fluid index implies the excretion of urine from at least one kidney. Decreasing amniotic fluid volume on serial ultrasound usually indicates deteriorating renal function. Furthermore, renal function can be assessed by the sonographic appearance of the renal parenchyma and by the laboratory analysis of fetal urine via percutaneous bladder aspiration. The presence of cortical cysts or increased echogenicity is highly predictive of renal dysplasia, but the absence of these findings does not exclude it.⁹⁹ Normal fetal urine chemistry includes a urinary sodium less than 100 mEq/dL, chloride less than 90 mEq/dL, osmolality less than 200 mOsm/L, and β_2 -microglobulin less than 4 mg/dL. Values greater than these suggest that the fetal kidney is unable to reabsorb these molecules and predict poor postnatal renal function.

The greatest challenge is selecting fetuses that have severe urinary obstruction yet reversible or

salvageable renal function. Presently, selection criteria for fetal intervention are a male fetus less than 30 weeks' gestation with evolving oligohydramnios, normal renal function, and no associated anomalies. Fetuses older than this are best treated by postnatal approaches. If there is evidence of lung maturation, then early delivery is recommended. The goal of fetal therapy is to adequately drain the urinary obstruction and to restore normal amniotic fluid volume. Methods of urinary tract decompression include percutaneous vesicoamniotic shunt placement, fetoscopic or open vesicostomy, and fetoscopic fulguration of posterior urethral valves.^{100,101} Open fetal surgery, including vesicostomy or ureterostomy, has resulted in 50% survival, with two of eight children in one series having normal renal function.¹⁰² Today, the most widely used and accepted means of treating bladder outlet obstruction is percutaneous insertion of a double-J vesicoamniotic shunt. Placement of a vesicoamniotic shunt is associated with 50% survival, but shunt complication rates as high as 45% may result. Direct fetoscopic ablation of posterior urethral valves holds promise for the future, though currently limited data are available to assess selection criteria and outcomes for fetuses treated by this approach.

Twin-to-Twin Transfusion Syndrome

TTTS, present in 5% to 35% of monochorionic twin pregnancies, occurs when there is unequal sharing of the monochorionic placenta. Generally, this finding can be made on prenatal ultrasound, and often the communicating placental vessels can be characterized by Doppler. Arteriovenous anastomoses lead to a net shunting of blood from the donor to recipient. The donor twin often suffers intrauterine growth retardation, cardiac failure, and oligohydramnios, whereas the recipient twin may suffer polyhydramnios, cardiomyopathy, and fetal hydrops. The smaller twin's placental cord insertion is often marginal or velamentous, whereas the larger twin's cord inserts into the placenta centrally.¹⁰³ Quintero et al.¹⁰⁴ have described a staging system for this condition. In stage 1, polyhydramnios and oligohydramnios occur, but the donor bladder is still visible. In stage 2, the bladder is no longer visible, and in stage 3 abnormal Doppler signals are detected in the respective umbilical arteries or veins. Stage 4 is characterized by findings of hydrops, and stage 5 is fetal death. In addition to the Quintero staging, recent studies suggest that comprehensive cardiac assessment by echocardiography may improve patient risk stratification.⁹ Overall, TTTS before 26 weeks' gestation is associated with a high rate of fetal loss and perinatal death and a high incidence of brain damage in survivors.^{105,106} In severe forms of TTTS, perinatal mortality rates of up to 90% have been reported.¹⁰⁷

Treatment options include aminoreduction of the recipient sac, amniotic membrane septostomy, and fetoscopic ablation of communicating vessels.^{108–110} Recently, endoscopic laser coagulation has become the treatment of choice for severe TTTS diagnosed before 26 weeks' gestation. In a multicenter European trial, twins with severe TTTS of all Quintero stages were randomized to undergo fetoscopic laser ablation or standard amnioreduction therapy. The trial was stopped after 142 women were randomized, because of the clear benefit of the laser approach. Endoscopic laser ablation led to improved outcomes in all variables examined, including increased fetal survival and decreased incidence of neurologic complications.¹⁰⁵

Congenital Heart Defects

Fetal intervention may play a role in the management of some fetuses with rare congenital heart defects, including those with severe aortic or pulmonary stenosis, and hypoplastic left heart syndrome with intact or highly restrictive atrial septum.^{111–113} There is evidence that fetuses with aortic or mitral valve stenosis may progress to hypoplastic left heart syndrome, presumably as a result of decreased ventricular filling. Furthermore, critical pulmonary stenosis or atresia with intact ventricular septum may progress to the so-called "hypoplastic right heart syndrome." Staged palliative surgery is the only therapeutic option for newborns with these conditions, and mortality remains significant. The goals of fetal intervention for these anomalies are to relieve the obstruction, restore normal cardiac physiology, and reverse the progression toward ventricular hypoplasia. In an initial report from investigators at Children's Hospital, Boston, in which 20 fetuses underwent balloon dilation of a stenotic aortic valve at 21 to 29 weeks' gestation, five fetuses died following the procedure.¹¹³ Of 14 who were thought to have a technically successful procedure, 3 had evidence of a two-ventricle heart postnatally, thus supporting the experimental rationale. More recently, Tworetzky reported the predictors of technical success and postnatal biventricular outcome after in utero aortic valvuloplasty in 70 fetuses. The technical success rate was 74%, and 17 had biventricular circulation postnatally. The authors developed a multivariable threshold scoring system allowing highly sensitive and moderately specific identification of fetuses able to survive postnatally with a biventricular circulation.¹¹⁴ Tworetzky also reported the outcomes of in

utero atrial septoplasty in fetuses with hypoplastic left heart syndrome. Of 21 procedures attempted, 19 were technically successful. Although the authors could not conclude that this particular procedure improved survival given the small patient size, they did find that creation of a defect greater than 3 mm was associated with better postnatal oxygenation and less frequent need for emergent postnatal intervention.¹¹¹

Fetal Intervention for Other Anomalies

Fetal intervention is indicated for a number of other fetal conditions, including amniotic band syndrome and twin-reversed arterial perfusion (TRAP) sequence. Fetoscopic lysis of constricting amniotic bands may lead to limb salvage and improved outcome.^{115–117} Similarly, in the TRAP sequence, fetoscopic ligation or ablation of the acardiac twin's umbilical cord is the treatment of choice.¹¹⁸

FUTURE OF FETAL INTERVENTION

There will always be a role for fetal intervention in the treatment of certain specific congenital structural abnormalities. The exact nature of this role, however, is under constant reevaluation and change. The primary goal of fetal therapy is to improve the outcome of the affected fetus while minimizing maternal risks. If fetal outcomes can be improved by alternative means, such as lung liquid ventilation or other postnatal therapies that pose no risks to the mother, then indications for fetal therapy will decrease. On the other hand, as the risks and complications of fetal surgery continue to decrease, such as those related to preterm labor and chorioamniotic membrane separation, then the role for fetal interventions may increase. Increased miniaturization of fetoscopic equipment and optics, advances in robotics, newer approaches to closure of the uterus and fetal membranes, and advances in our understanding and treatment of preterm labor will enhance our ability to change the outlook for an increased number of fetuses with congenital malformations.

Chapter 101

Pediatric Head and Neck

Laura L. Neff and Reza Rahbar

Key Points

- 1 Infants are obligate nasal breathers for the first 3 to 6 months of life; therefore, any nasal obstruction can cause respiratory distress.
 - 2 The site of the neck mass is important (midline vs. lateral) for narrowing the differential diagnoses.
 - 3 Benign cervical lymphadenopathy is the most common neck mass in the pediatric population.
 - 4 Although rare, always consider malignancy to avoid delay in diagnosis.
 - 5 History is important in the work up and treatment of an airway foreign body.
-

INTRODUCTION

Lesions of the head and neck in the pediatric population result from a wide range of etiologies. In contrast to the adult population, the majority of pediatric neck masses are benign with only 11% of neck masses demonstrating a malignancy on biopsy.¹ In pediatrics, neck masses can be congenital, infectious, inflammatory, traumatic, lymphovascular, or neoplastic in etiology. Neck masses can range in presentation from an asymptomatic lesion to acute respiratory distress, depending on their size and location. Inflammatory cervical lymphadenitis is the most common cause of pediatric neck masses found in children. Congenital masses, such as branchial cleft cysts and thyroglossal duct cysts (TGDC), often become clinically apparent when infected. Malignant processes are rare in children, and the most common malignancy seen in the pediatric neck is lymphoma. This chapter will focus on the most common head and neck pathologies found in the pediatric population along with their clinical presentation and treatment.

Imaging

Imaging is not always required for the diagnosis of a pediatric neck mass, but can be helpful in clarifying extent and size, location to vital structures, and radiologic characteristics of a lesion. Ultrasound (US), computed tomography (CT), or magnetic resonance imaging (MRI) can be helpful in narrowing the differential, but often a biopsy or excision is still required for diagnosis.

US is a good first choice for imaging of palpable lesions such as salivary gland tumors or thyroid nodules. The pediatric neck often has less subcutaneous adipose tissue, which leads to better imaging with ultrasonography.² US offers the ability to differentiate solid from cystic lesions, and color Doppler can determine the presence and characteristics of vascular flow within a mass.³ US can be very helpful in determining the stage of an abscess, helping to differentiate early lymphadenopathy that can be treated with antibiotic therapy from a mature abscess that requires surgical drainage. US has the advantages of being portable, fast, does not require sedation, and does not expose the pediatric patient to ionizing radiation. Disadvantages of US include variability of the technician's skill/experience as well as lower resolution images.

CT scans and MRI provide a more detailed study of the anatomy of the neck. CT scans are readily available in emergent situations with scans completed quickly for patients who are critically ill. This speed can also help to eliminate the need for sedation and help to minimize artifact from movement. CT scans offering more osseous detail such as remodeling or erosion, as well as calcifications. The main disadvantage of CT scans is the exposure to ionizing radiation, which could potentially have carcinogenic effects in the long term.⁴⁻⁶ Newer techniques offer reduced exposure with CT scans, but MRI and US should be utilized when appropriate.

MRI is the scan of choice for neck masses due to excellent soft tissue detail and avoidance of ionizing radiation. Details of the margins and possible neural spread or intracranial extension of a mass can be noted with the use of a contrast-enhanced MRI. The longer length of time required to obtain an MRI

often requires sedation due to concerns of movement artifact in the pediatric population, which is the main disadvantage of the MRI.

To help with evaluating, staging, and monitoring a solid tumor, ¹⁸F fluorodeoxyglucose PET (FDG-PET) is a noninvasive tool to evaluate malignancies in children. FDG-PET has the advantage of being able to differentiate recurrent or residual tumor from changes related to treatment. PET scans do expose children to ionizing radiation and also may require sedation. It is also important to keep in mind that certain tissues have a higher uptake of FDG, including the adenoids, tonsils, thymus, brown adipose tissue, bone marrow, and the spleen.^{7,8}

Congenital

Congenital lesions of the head and neck are diverse and often the location of the lesion can greatly assist in narrowing the diagnosis. For example, midline lesions include TGDCs and der-moid cysts, whereas lateral neck lesions have a much broader differential.

Branchial Anomalies

The branchial apparatus in the fetus eventually develops into head and neck structures. Any deviation in the development of these structures can result in an anomaly that can present as a mass in the neck. Depending on the part of the branchial apparatus that is involved, the mass can present in different parts of the neck. Sinus tracts and fistulas tend to present at a younger age due to their physical appearance, whereas cysts usually present when they get infected and enlarge. A sinus tract has an external opening to the neck, whereas a fistula has an external and internal opening. Cartilaginous remnants can also be found in the neck.

Figure 101-1. CT or MRI of second branchial cleft cysts.

These lesions often present with infection, and it is best to minimize inflammation and infection with antibiotics prior to excision, making the dissection and identification of important structures easier. Abscesses can be treated with minimal intervention, such as needle aspiration or if needed, incision and drainage. During the procedure, it is important to communicate with anesthesia to avoid paralysis for proper nerve monitoring. Radiologic imaging with CT or MRI can be helpful (Fig. 101-1). Rates of recurrence for branchial cleft cysts is quoted around 3%, but this increases to 20% in cases that have undergone a prior attempt at excision.⁹

Anatomy and Embryology

The branchial arches form during the fourth to eighth week of gestation as four pairs of well-developed ridges with associated clefts. Each has a cartilaginous center (mesoderm), a cleft (ectoderm), an internal pouch (endoderm), and a nerve (Table 101-1). These structures mature into the major structures of the head and neck (Fig. 101-2).

Table 101-1 Pharyngeal Arch Structures

Pharyngeal Arch	Muscular Contributions	Skeletal Contributions	Nerve	Artery
1st (mandibular arch)	Muscles of mastication, anterior belly of the digastric, mylohyoid, tensor tympani, tensor veli palatini	Premaxilla, maxilla, mandible (only as a model for mandible not actual formation of mandible), zygomatic bone, part of the temporal bone, the incus, and the malleus of the middle ear, also Meckel cartilage and the sphenomandibular ligament.	Trigeminal nerve (V2 and V3)	Maxillary artery, external carotid artery
2nd (hyoid arch)	Muscles of facial expression, buccinator, platysma, stapedius, stylohyoid, posterior belly of the digastric, auricular	Stapes, temporal styloid process, hyoid (lesser horn and upper part of body), stylohyoid ligament, Reichert cartilage	Facial nerve (VII)	Stapedial artery, hyoid artery
3rd	Stylopharyngeus	Hyoid (greater horn and lower part of body), thymus, inferior parathyroids	Glossopharyngeal nerve (IX)	Common carotid, internal carotid
4th	Cricothyroid muscle, all intrinsic muscles of soft palate (including levator veli palatini) <i>except</i> tensor veli palatini	Thyroid cartilage, superior parathyroids, epiglottic cartilage	Vagus nerve (X), superior laryngeal nerve	Right 4th aortic arch: subclavian artery Left 4th aortic arch: aortic arch
6th	All intrinsic muscles of larynx except the cricothyroid muscle	Cricoid cartilage, arytenoid cartilages, corniculate cartilage, cuneiform cartilages	Vagus nerve (X), recurrent laryngeal nerve	Right 6th aortic arch: pulmonary artery Left 6th aortic arch: pulmonary artery and ductus arteriosus

Figure 101-2. Derivation of various areas of the head and neck from the branchial arches and clefts of the embryo.

First branchial cleft anomalies, which comprise 8% of branchial cleft anomalies, are divided into type 1 and type 2.¹⁰ Type 1 branchial cysts often present as a fistula around the conchal cartilage. The tract can follow the course of the external auditory canal and is lined by squamous epithelium.¹¹ Type 2 branchial lesions are found near the angle of the mandible and are composed of both epithelium and mesoderm (as opposed to only epithelial elements in type 1). Both type 1 and type 2 first branchial cleft anomalies can be closely associated with the facial nerve, although type 2 lesions are more likely to be intimately involved with the nerve. Type 2 branchial lesions can loop under the facial nerve, pushing it laterally and inferiorly.¹² The tract for a first branchial cleft usually extends from the opening near the mandible, near the posterior aspect of the parotid, and toward the external auditory canal. One should monitor the facial nerve at all times, with visualization of the face during the entire excision and avoidance of paralysis with anesthesia.

The most common branchial anomaly is derived from the second branchial cleft groove, representing 90% of branchial cleft anomalies.¹³ It can occur as an isolated cyst or as a sinus tract/fistula that extends from the cervical skin to the tonsillar fossa. The cysts will often present at the time of an upper respiratory tract infection as an enlarging, tender mass. If a fistula is present, it will course through the internal and external carotid arteries, over the hypoglossal and glossopharyngeal nerves to end in the

tonsillar fossa. A cyst can occur anywhere along this tract, but most commonly occurs in the anterior triangle of the neck below the hyoid.

Third and fourth branchial cleft lesions are rare. Third branchial cleft cysts present low and anterior in the neck. Fistulas can course from the piriform fossa and drain to the anterior cervical skin. This tract pierces the thyrohyoid membrane and tracks under the glossopharyngeal nerve and internal carotid artery, but stays above the vagus nerve. These lesions can be intimately involved with the thyroid, and sometimes a hemithyroidectomy is required for repeated recurrences. An infected TGDC or third branchial cleft cyst may be the cause of suppurative thyroiditis in children.¹⁴ The external location for a fourth branchial cleft is the same as the second and third, but the internal opening is near the apex of the piriform sinus. Fourth arch masses are extremely rare and but reports do exist. Third and fourth branchial sinus/tract dissections are similar to a second branchial cleft. Endoscopy at the beginning of the case can greatly assist in locating and resecting the tract. One promising surgical option for third or fourth sinus tracts is cauterization or sclerotherapy.¹⁵

The standard treatment for all types of branchial anomalies is complete surgical excision. The surgery is performed under general anesthesia and the patient is positioned with the neck slightly extended with a shoulder roll. If there is a sinus tract or fistula present, a small ellipse is made around this opening after it has been cannulated with a small lacrimal probe. A probe can be used or some use a small injection of methylene blue, although this can be messy. The tract is then dissected cephalad until the end of the sinus tract or until the internal opening of the fistula is reached. The dissection for the most common branchial cleft anomaly, the second branchial cleft, penetrates the platysma, rises along the carotid sheath and turns medially near the branches of the internal carotid artery and courses between the posterior belly of the digastric muscle and stylohyoid muscle, and over the hypoglossal nerve before ending near or in the tonsillar fossa. The tract is then ligated with absorbable suture. Often a direct laryngoscopy or simply a finger placed in the oropharynx can help to visualize the course of the tract and assist with dissection. Some patients might require a “stepladder” incision to trace the tract superiorly (Fig. 101-3).

Cartilaginous remnants are normally small and present in the subcutaneous tissue along the anterior border of the sternocleidomastoid, are usually palpable and easily resected. These rarely get infected and removal is for cosmetic indications.

Preauricular cysts, pits, and sinuses are common in children and are thought to develop from the first two branchial arches. They are more common and more often bilateral in comparison to first branchial cleft cysts and rarely become infected. The tracts extend from the skin down to the helical cartilage of the auricle and are lined with squamous epithelium. Treatment is surgical excision and the recurrence rate ranges from 19% to 40%.¹⁶

Figure 101-3. Picture of sinus tract.

Figure 101-4. Locations of thyroglossal duct cysts.

Thyroglossal Duct Cysts

TGDCs are congenital lesions that develop from the thyroglossal duct tract that occurs during the descent of the thyroid. The thyroid descends from the foramen cecum at the sixth week of gestation and tracts along the anterior neck in close association with the developing hyoid bone. This tract usually involutes, but if it persists the tract can present as a TGDC at any point from the foramen cecum to the thyroid (Fig. 101-4). TGDCs are the most common neck mass besides benign lymphadenopathy in the pediatric population.¹⁷ Physical presentation reveals a midline neck mass that may move with protrusion of the tongue (Fig. 101-5). US is useful to look at the characteristics of the cyst, but is most important to determine if there is a normal thyroid gland present. In rare cases, the TGDC could be the sole functioning thyroid tissue in the patient.

Figure 101-5. Thyroglossal duct cyst.

Treatment is surgical excision and removing the entire tract with a core of tissue and the central portion of the hyoid bone can minimize recurrence. Rarely, papillary thyroid carcinoma can be found in the specimen.¹⁸ The procedure is performed under general anesthesia with the neck extended and placement of a shoulder roll. A horizontal skin incision is made over the cyst, with no need to excise skin unless a fistulous tract or infection has involved the dermis. Careful dissection around the cyst then allows continued dissection superiorly toward the hyoid bone. Muscular attachments to the central hyoid bone are removed with cautery and the hyoid is removed en bloc with the cyst and tract. A core of tissue is then removed above the hyoid bone toward the base of tongue. The tract is then ligated with absorbable suture. Placing a gloved finger at the base of tongue can sometimes facilitate this maneuver.

The wound should then be irrigated copiously and closed in a layered fashion. A drain is often used. Complete excision is considered curative and TGDCs have a recurrence rate of less than 10% when using this method.¹⁷

Other midline lesions to keep in the differential include dermoid and epidermoid cysts, lymph nodes, thymic cysts, and bronchogenic cysts.

Dermoid Cysts

Dermoid cysts should be considered in the differential of any midline lesion, although they can be off midline as well. On examination, dermoid cysts present as firm masses that are soft, mobile, nontender, and grow slowly. Dermoid cysts contain tissue from the three germinal layers, which can include sweat glands and sebaceous glands. Treatment is total surgical excision. If a nasal dermoid occurs, it can penetrate the bone and a CT or MRI should be performed to rule out intracranial extension. Midline dermoid cysts are likely entrapped epithelium at the time of embryonic fusion.¹⁹

Thymic Cysts

Lesions of the thymus usually occur in the lower neck, but can present anywhere from the piriform sinus to the chest. The differential includes thymic cysts, thymic hyperplasia, or thymoma.

Infectious

The most common cause of a neck mass in the pediatric population is benign cervical adenopathy. Cervical lymph nodes are palpable in 40% of infants and 55% of pediatric patients on examination.^{20,21} Lymph nodes that are less than 1 cm in size and asymptomatic are considered normal in children less than 12 years of age.¹⁴ Lymphadenitis is most commonly seen in the submandibular region and cervical nodes, and the source of infection can be viral, bacterial, fungal, or neoplastic. Bacterial and viral infections causing upper respiratory infections are the most common cause of cervical lymphadenopathy. Other possible sources of cervical LAD include fungal (in immunocompromised patients), cat scratch disease, mononucleosis, atypical mycobacterium, and tuberculosis. As mentioned previously, lymphomas or metastatic disease can also present with nodal enlargement in the neck. Although rare, one should also consider Kawasaki disease, sarcoidosis, Rosai–Dorfman syndrome, and histiocytosis X.

Acute suppurative lymphadenitis is most common in the 6-month to 3-year range, with lymph node enlargement associated with an upper respiratory tract infection. The most common etiologies include *Staphylococcus aureus* and group A beta-hemolytic streptococci. There is commonly overlying skin changes with erythema and cellulitis, with an associated leukocytosis and fever. The lymph node enlarges and eventually outgrows the blood supply, resulting in central necrosis. Management can sometimes include needle aspiration of purulence, but often requires an incision and drainage with placement of a drain or packing under anesthesia. An incision is made in the area of fluctuance and blunt dissection should break up all loculations. It is important to place the incision in a place that minimizes risk to vital structures, such as the facial nerve, and allows for the best cosmesis. Antibiotics are geared toward *Staphylococcus* and *Streptococcus* but cultures should be taken with a change in antibiotic therapy if necessary. The induration from the abscess can take several weeks to resolve, but recurrence is rare. If the abscess recurs, it should prompt investigation of a possible underlying anomaly. Viral infections rarely cause suppurative adenitis.

Lymphadenitis can also be chronic or subacute with enlargement of lymph nodes not associated with an acute infection, although sometimes can occur in a patient with recurrent URIs, tonsillitis, otitis media, or allergic rhinitis. Often the lymph node is solitary, nontender, and mobile. Excisional biopsies are recommended generally when the lymph node is larger than 2 cm and has been present for longer than 8 weeks, or has concerning characteristics such as immobility or rapid growth. Once excised, it is important to obtain cultures, histopathology, and flow cytometry.

Mycobacterial infections, usually caused by the atypical mycobacterium *Mycobacterium avium-intracellulare-scrofulaceum* (MAIS) complex, can be very challenging to manage. The pathogens are usually acquired through the mucous membranes during the eruption of teeth, not through person-to-person transmission. These lesions often cause discoloration of the skin and can fistulize over time (Fig. 101-6). Antibiotic therapy is not always curative. It most commonly occurs in children 1 to 5 years of age and often has associated asymptomatic lymphadenopathy but no fever or leukocytosis. The response to antibiotic therapy can be disheartening with little improvement and sometimes surgery is required to excise the infection. Adjuvant treatment with clarithromycin or rifabutin is often indicated, as is a consultation with the infectious disease team. In contrast, children with *M. tuberculosis* usually have

fever and respiratory symptoms along with positive findings on chest x-ray and the purified protein derivative skin test.

Cat scratch disease, caused by *Bartonella henselae*, can cause tender cervical lymph node enlargement in 25% of cases. Usually there is a history of contact with a cat within 2 weeks of the development of tender lymphadenopathy. The site of inoculation is usually an extremity. The diagnosis can be made using *B. henselae*-based serologic indirect fluorescent antibody test or enzyme immunoassays. The disease is usually self-limited with resolution in 2 to 8 weeks and no antibiotic therapy is necessary; however, rarely patients can suffer disseminated disease.²²

Figure 101-6. Atypical mycobacterium infection.

Vascular Malformations

Infantile Hemangioma

Infantile hemangiomas (IH) are the most common tumor of infancy. IH are endothelial tumors characterized by an increased proliferation and turnover of endothelial cells, which differentiates this from other vascular malformations. IH grow rapidly during the first 9 months (proliferative phase) and then slowly regress (involuting phase). Regression is usually complete by 4 to 5 years of age.²³ They can occur anywhere in the body, with frequent involvement of the tongue and parotid gland. Usually hemangiomas occur as a solitary lesion, but 20% of patients can have multiple affected sites. On examination, hemangiomas are a well-demarcated, raised, red mass that blanches with pressure (Fig. 101-7). Known risk factors include female sex, Caucasian race, preterm birth, and low birth weight. Most hemangiomas are not visible at birth but become apparent in the first few months of life and 90% are noticeable by 6 months of age.²⁴ Hemangiomas can occur in the subglottic region and present with biphasic stridor, presenting between 1 and 3 months of age. Similarly, parotid hemangiomas present as an enlarging mass within the parotid gland at age 1 to 3 months. Evaluation by Doppler US showing fast-flow is diagnostic.

Treatment for most IH is conservative, as 90% are small, localized, and not problematic. IH can ulcerate, bleed, and cause deformities and in these cases local wound care can help and sometimes intralesional steroid injections may be necessary.²⁵ Injection with steroids can stabilize the growth of IH in 95% of patients and decrease the size in 75% of patients.²⁶ Systemic corticosteroid treatment can be used for large lesions that become symptomatic and are not amenable to injection. Propranolol has also been used in the treatment of IH with varying results. Patients must be monitored closely while on propranolol therapy due to possible serious side effects.

Figure 101-7. Hemangioma.

Figure 101-8. Picture of a patient with lymphatic malformation.

Lymphatic Malformation

Lymphatic malformations (LMs) are slow-flow vascular anomalies and 75% of LMs present in the head and neck. The incidence ranges from 1 in 2,000 to 4,000 births and usually occurs in the first decade of life. The lymphatic system develops around week 5 of gestation and although the mechanism for the development of an LM is not completely understood, it is generally thought to occur due to parts of the lymphatic system that fail to establish connections with the main lymphatic system or venous channels (Fig. 101-8). Histopathology of LMs shows progressive dilation of abnormal vessels and LMs are composed of vascular spaces filled with eosinophilic and protein-rich fluid. LMs are present at birth, but sometimes are not apparent until enlargement due to infection or trauma with hemorrhage. Some patients are diagnosed with LM when found on prenatal US, and can potentially obstruct the airway and may require an ex utero intrapartum treatment procedure (EXIT procedure).

LMs are divided in microcystic, macrocystic, and mixed lesions. Microcystic lesions are usually above

the mylohyoid and can involve the floor of mouth, tongue, parotid, and lip. These lesions have poorly defined borders and infiltrate nearby muscle and fatty planes. Macrocystic lesions are usually below the mylohyoid and have multiple large, loculated cysts in varying size and shape. LMs can enlarge with infection or trauma, which can lead to airway obstruction, functional issues (swallowing, speech), or deformity. Imaging can be helpful to determine the extent of the lesion as well as involvement of surrounding structures.

Treatment for these lesions is challenging and the main options include observation, sclerotherapy, or surgery. LMs are benign lesions and this must be kept in mind when planning treatment. Macrocystic lesions are more amenable to both sclerotherapy and surgical excision, whereas complete removal of microcystic lesions would often result in unacceptable morbidity due to their infiltrative nature. Subtotal resection leads to a high recurrence rate and surgery can be difficult due to previous inflammation and scarring from sclerotherapy. Radiofrequency ablation can be useful in relief of ulceration tongue lesions or oral mucosa.²⁷ The CO₂ laser can help with symptomatic lesions of the airway or oral cavity, which can reduce bleeding and ulceration. Recently, rapamycin or “sirolimus” has been investigated as a possible oral medication for LMs with encouraging preliminary results.²⁸

Airway

Airway obstruction can occur from congenital or acquired lesions at any level from the nose to distal airway. Children can present with tachypnea, dyspnea, and chest-wall retractions and it is imperative to establish an airway while investigating the potential causes with history and physical, chest radiograph, and arterial blood gas if appropriate. Laryngoscopy and bronchoscopy are often warranted.

Infants are obligate nasal breathers and nasal obstruction, especially bilateral obstruction, can cause acute respiratory distress at birth. Choanal atresia or stenosis, piriform aperture stenosis, or nasal septal deviation can cause significant obstruction. Piriform aperture stenosis is a narrowing of the anterior nasal passageway that can also cause similar symptoms to choanal atresia. Nasal obstruction can also result from lesions such as a nasolacrimal duct cyst, encephalocele, or nasal glioma. Nasal examination and sometimes a CT scan can help to determine the diagnosis.

Macroglossia or retrognathia/micrognathia may also cause obstruction of the oral cavity in the infant. In the oropharynx, a TGDC, a vallecular cyst, or lingual thyroid can cause airway obstruction.

In the supraglottic region, laryngomalacia can affect the larynx in newborns. Laryngomalacia results from immature cartilage in the larynx and discoordination of the arytenoids and epiglottis. The diagnosis is made using a flexible laryngoscope and viewing the larynx while the patient is awake. High-pitched inspiratory stridor that is worsened with exertion, crying, or excitement is the classic description. Most children do not require any intervention, but a supraglottoplasty can be performed when laryngomalacia causes breathing or feeding difficulties. There are many different variations of the supraglottoplasty, but the basic concept is to remove excess or floppy supraglottic tissues to improve the airway.

At the level of the glottis, obstruction can occur for several reasons, including vocal cord paralysis and glottis webs. Bilateral vocal cord paralysis can present with a normal cry but biphasic stridor, whereas unilateral vocal cord paralysis usually presents with a weakened cry and no respiratory distress. A mediastinal lesion should be ruled out in patients with vocal cord paralysis and patients with bilateral vocal cord paralysis warrant a neurologic consultation for possible Arnold–Chiari malformation or hydrocephalus. A tracheotomy may be necessary for patients with bilateral vocal cord paralysis if they are in respiratory distress.

Glottic webs usually affect the anterior portion of the vocal cords and can range from a thin membrane to a thick web that can extend inferiorly to the subglottis. Patients present with dysphonia and sometimes respiratory distress. Treatment is dependent on the extent of the glottis web, which can be divided endoscopically in the majority of cases.²⁹

The subglottis is the narrowest part of the airway in an infant due to the cricoid cartilage. Stenosis can occur congenitally or can be acquired after long-term intubation. Subglottic hemangiomas are another source of airway obstruction that enlarge after birth and are associated with cutaneous hemangiomas. The subglottic hemangiomas can occur as an isolated lesion or as part of the PHACES syndrome (posterior fossa malformation, arteriovenous malformations, cardiac/aortic defects, eye anomalies, and sternal defect). Treatment can be systemic or intralesional corticosteroids, laser therapy via endoscopic approach, or open excision.

In patients with a prior intubation, one or multiple subglottic cysts may form and cause airway obstruction. Treatment entails endoscopic evaluation with marsupialization or removal with a laser or

laryngeal microdebrider.

Tracheomalacia can occur in a primary or secondary form. Primary tracheomalacia is a rare congenital disease in which the tracheal cartilages collapse on expiration. Most cases of primary tracheomalacia are mild and no intervention is required, although if severe a tracheostomy may be required. Secondary tracheomalacia occurs when an extrinsic compression causes collapse of the trachea on expiration. Treatment is then tailored to the source of compression, whether a vascular anomaly or mass.

Tracheal stenosis can occur due to congenital complete tracheal rings and can involve a segment or the entire trachea. Depending on the extent of the stenosis, a tracheal resection or a slide tracheoplasty may be performed.

Acquired obstruction of the airway includes infectious sources, such as epiglottitis, and foreign-body aspiration. Although rare, epiglottitis is a life-threatening disease caused by *Haemophilus influenza* type B (90% of cases) that occurs most commonly in children ages 2 to 4 years. The *H. influenza* vaccination has reduced the number of cases, but pneumococci and B-hemolytic streptococci can also cause epiglottitis. The disease presents rapidly, with stridor, airway obstruction, drooling, odynophagia, fever, tachypnea, and tachycardia. As the disease progresses, the child will often assume the “tripod” position by leaning forward, drooling, and suffering from air hunger. It is important not to agitate the patient and obtain an airway in the operating room with a tracheostomy set available. Depending on the stability of the patient, a lateral neck film can confirm the diagnosis with the “thumbprint” sign demonstrating an edematous epiglottis. The patient should be started on antibiotic therapy and laryngoscopies performed until the patient’s epiglottis/airway edema allows for a safe extubation.

Airway foreign bodies can be life threatening and the history is of utmost importance. Combining the convincing history of a coughing/choking episode with an abnormal chest radiograph warrants a bronchoscopy. Sometimes a bronchoscopy is warranted on the history alone, as less than half of the patients with an airway foreign body have an abnormal chest radiograph.³⁰ If it was a witnessed aspiration, obtaining a detailed description of the object and practicing with the bronchoscopy foreign-body forceps on a similar object can be helpful if the patient is stable.

Chapter 102

The Pediatric Chest

Mary C. Santos and Robert E. Cilley

Key Points

- 1 Pectus excavatum repair should occur in late childhood or adolescence and is now most frequently performed with a rigid transversely oriented pectus excavatum bar that pushes the deformity back into place.
 - 2 Pectus carinatum occurs less frequently than pectus excavatum and does not cause physiologic impairment; bracing has become the method of choice for treatment.
 - 3 Pulmonary sequestrations (PSs) are abnormal lung tissue with anomalous systemic blood supply that can be either intralobar or extralobar lesions based on their relationship with the investing visceral pleura and adjacent normal lung tissue. They do not communicate normally with the trachea or a bronchus.
 - 4 Congenital cystic adenomatoid malformations (CCAMs) have a normal vascular supply and communicate with the normal tracheobronchial tree. They result from excessive proliferation of bronchial structures without the development of the corresponding alveoli. Management of asymptomatic CCAMs remains controversial.
 - 5 Benign cysts of the mediastinum are relatively common and include thymic cysts, enterogenous cysts, dermoid cysts, lymphatic malformations (cystic hygromas), and pericardial cysts. Resection is usually recommended because of the possibility of progressive enlargement with compression, hemorrhage, or infection.
 - 6 Primary lung tumors in children are rare and include bronchial adenoma, pulmonary blastoma, inflammatory pseudotumor (composed of inflammatory cells), hamartoma and rarely bronchoalveolar carcinoma. Resection is generally the appropriate initial therapy.
 - 7 Metastasectomy for many solid embryonal neoplasms can improve survival if the primary disease is controlled by resection.
 - 8 Tracheoesophageal fistula can occur as esophageal atresia with proximal pouch and distal tracheoesophageal fistula (most common, at 85% to 95%), esophageal atresia without fistula (5% to 7%), tracheoesophageal fistula without esophageal atresia H type (2% to 6%), and rarer forms of this anomaly including esophageal atresia with proximal tracheoesophageal fistula and esophageal atresia with both proximal and distal tracheoesophageal fistula.
 - 9 Approximately 75 children die from foreign-body aspiration or ingestion each year. Bronchoscopic evaluation and foreign-body removal are performed in the operating room under general anesthesia, where the rigid bronchoscope with optical forceps can be used to remove most aspirated foreign bodies safely.
 - 10 Congenital diaphragmatic hernia (CDH) is a physiologic emergency and not a surgical emergency. The newborn with CDH should be stabilized by nonsurgical means and delayed, well-planned surgical repair undertaken subsequently.
-

CHEST WALL DEFORMITIES

Deformities of the chest wall may be obvious at birth but often become more noticeable at the time of preadolescent and adolescent growth. The physical appearance may vary from barely detectable to grotesquely deforming. Although there may be some physiologic benefit from surgical correction of these deformities, restoration of a more normal appearance is equally important in the decision to operate. The impact of these deformities on normal psychosocial development, as well as the less certain evidence of cardiorespiratory impairment, constitutes adequate justification in the affected child.

Embryology, Development, and Etiology of Chest Wall Deformities

In the embryo, the ribs are derived from individual somites as mesoderm differentiates into cartilage and advances ventrally toward the developing sternum. The rib cartilage eventually approaches the sternum. The sternum itself is derived independently from two parallel bands of mesoderm that develop away from the midline. The two sternal bands fuse in a cranial-to-caudal direction and become progressively chondrified. Transverse divisions of the cartilaginous sternum differentiate into segments opposite each end of the rib pairs. At birth, small ossification centers are present in the sternum and the ribs have largely ossified. Final ossification is usually complete by mid adolescence. The process is sufficiently predictable that sternal ossification is a reliable method of determining bone age. There is a sharp demarcation in each rib between the ossified portion and the cartilaginous portion, with the latter becoming ossified only much later in life. The etiology of chest wall deformities is poorly understood.¹ Explanations include abnormal intrauterine pressure applied to the chest, abnormalities of diaphragmatic development, connective tissue abnormalities, and genetic predisposition. Abnormal, excessive, or asymmetric growth of the costal cartilages associated with the 3rd to 10th ribs is most implicated.² Sternal clefts are understood as a failure of fusion of some portion of the sternal bands.

Pectus Excavatum

Pectus excavatum from the Latin “hollowed chest” is the most common deformity of the anterior chest wall occurring in 1 in 400 to 1 in 1,000 children and accounting for more than 87% of chest wall deformities. A family history is present in 45% of patients.^{2,3} Pectus excavatum results from abnormal regulation of the growth of the costal cartilages. There is a corresponding posterior curve in the body of the sternum beginning at the manubrium and extending to the xiphoid. The deformity is rarely precisely symmetric, with one side (usually the right) slightly more curved in than the other. Asymmetry may be pronounced with the sternum rotated nearly to the sagittal plane. The deformity may be apparent at birth but may become more apparent during growth and development, particularly during adolescence. Pectus excavatum occurs more frequently in males than females. Scoliosis is present at increased incidence in this population although rarely requires surgical correction. Patients often have an asthenic build and stoop-shouldered posture. Marfan syndrome predisposes to pectus excavatum. The diagnosis of Marfan syndrome should be considered when patients are referred for evaluation of a chest wall deformity.

At the time of surgical consultation, concerns about the cardiopulmonary implications of the chest wall deformity are often paramount in the mind of the referring physician as well as the family. Many patients will have complaints of chest pain and/or shortness of breath. Most patients are disturbed by the appearance of the deformity, and some may be profoundly depressed and dysfunctional. The physiologic consequences of the deformity are less certain. Invasive and echocardiographic assessment of cardiovascular performance has demonstrated improvement in cardiac function and resolution of mitral valve prolapse in some patients following surgical correction of pectus excavatum. Studies have also demonstrated improved body image and subjective physical ability.^{2,5-9} The cardiorespiratory benefits of the repair remain controversial with more recent studies demonstrating improvement after bar removal especially with dynamic testing.⁹ Multiple studies of patient and parent satisfaction have demonstrated very well to excellent results.^{2,5,8-12} Clinical assessment of the severity of the deformity has included chest radiographs, computerized tomography (CT), caliper measurements, and contrast volume measurements of the cavity. The “pectus index” is defined as the ratio of the maximum internal transverse diameter of the thorax to the minimum sternovertebral distance.⁷ If cardiac disease is suspected on the basis of the history and physical examination, an echocardiogram may be indicated. Static pulmonary function testing is rarely helpful but exercise testing may be helpful.

Surgical Correction of the Pectus Excavatum

1 Although pectus excavatum is diagnosed in infants and young children, repair should be deferred to teenage years. This leads to improvement in cardiopulmonary status while avoiding recurrence and acquired thoracic dystrophy of early repair.

Traditional Operations

Traditional surgical correction is performed through an inframammary incision which is kept within the nipple lines (Fig. 102-1). The operation requires the exposure of costal cartilage by elevation of the pectoral muscles from the chest wall. The involved cartilages usually from 3 to 7 and parts of 8 to 10

are removed by subperichondrial excision, with careful preservation of the perichondrial sheaths. The xiphoid is detached from the sternum and the rectus muscles are detached inferiorly. The undersurface of the sternum is dissected free of the pericardium and pleura. A transverse wedge osteotomy is created in the sternum at the point where the sternum deflects posteriorly and the posterior surface is gently fractured but not displaced. A strut is usually placed beneath the sternum to maintain the position of the sternum. The strut is usually a stainless steel bar and is removed in 6 months to 1 year.^{2,4} The pectoral and rectus muscles are reapproximated. Closed suction drains are usually left in place in the submuscular layer. Patients are discharged when they are able to tolerate a diet and their pain is controlled by oral analgesics usually on the second to third postoperative day. Multimodal pain management including regional anesthesia, epidural analgesia, nonsteroidal anti-inflammatory agents, and narcotics are used. Complications may include pneumothorax not requiring therapy, wound seromas, and pleural effusions. Recurrence occurs in approximately 7% if repaired early but less than 2% undergo reoperation.² The incidence of reactive pectus carinatum after excavatum repair is 1%.¹³ Migration of implanted struts and bars has caused the most serious problems, including cardiac injury.

Figure 102-1. Pectus excavatum. **A:** Appearance of an adolescent male with a typical depression deformity. Note “stoop-shouldered” posture. **B:** Postoperative appearance at 6 months. Erect posture and subpectoral incision give a good cosmetic result.

The Minimally Invasive Repair/Nuss Procedure

Since the description of a technique not involving resection or osteotomy in 1998, the performance of the minimally invasive/Nuss procedure has gained widespread popularity. Using small lateral incisions, a rigid U-shaped bar is inserted transversely across the chest and then flipped and the sternum is pushed back into a normal position (Fig. 102-2).¹⁴ Modifications of the technique including the use of stabilizers, use of two bars, and routine use of thoracoscopy have been described.^{2,11,15} Reported complications have included pneumothorax, cardiac injury, bar displacement, chronic pain, pericarditis, and extraosseous bone formation.^{15–17} Postoperative pain management usually involves epidural analgesia as well as intravenous and oral medications, with a recent prospective study supporting epidural for early management and patient-controlled analgesia for later management.¹⁸ The bar is left in for up to 3 years during a period of development when most children are active and may engage in contact sports. Activity restrictions that are necessary while the bar is in place are not well defined. This technique is an important addition to the surgical treatment of chest wall deformities. Recent studies have demonstrated that the early-to-late teenage years are the appropriate time for repair.^{19,20}

Other Techniques

Implantation of submuscular silastic molds to alter the chest contour may result in a very acceptable appearance.²¹ This technique does not address any of the potential physiologic problems associated with pectus excavatum and has not been used widely.

Externally applied suction may also be used to treat depression deformities of the chest wall. Finally, implanted devices that use magnetic forces to pull the sternum forward show promise in correcting the defect in patients with pectus excavatum.^{22,23}

Pectus Carinatum

2 Pectus carinatum, from the Latin phrase for “keel,” is a chest wall defect where there is a protrusion of the sternum and ribs. This type of defect occurs less commonly than pectus excavatum and presents in approximately 1 in 1,000 to 1 in 1,500 teenagers. Physiologic impairment is absent; however, the concern for appearance may be even greater than with depression deformities of the chest wall. Protrusion deformities may be very difficult to hide even when fully clothed. Rapid growth of the costal cartilages occurring during puberty makes the deformity more pronounced at that time. Compression bracing has been described and is currently the first line of repair for pectus carinatum with surgery reserved for failures of therapy.²⁴⁻²⁹ Bracing is most successful with bracing for 16 to 20 hours per day. Surgery which involves the transverse sternal osteotomy or use of a minimally invasive technique with the bar passed anterior to the sternum.^{22,28}

Poland Syndrome

Named after the English surgeon Sir Alfred Poland, this rare congenital syndrome occurs in 1 in 30,000 births and includes a hypoplasia or aplasia of the thoracic wall components. These features include absence of the sternal portions of the pectoralis major muscle; absence of the pectoralis minor muscle; absence of portions of the serratus anterior and external oblique muscles; forearm and hand deformities; ipsilateral hypoplasia of the nipple, breast, and chest wall subcutaneous tissues; absence or deformity of the second to fifth costal cartilages; and absence of axillary hair on the affected side. Surgical treatment includes correction of any deformed ribs, formation of the anterior axillary fold using the latissimus dorsi muscle, and creation of the ipsilateral breast in females.^{30,31}

Figure 102-2. Thoracoscopically assisted Lorenz Bar insertion (Nuss procedure). **A:** Preoperative appearance with symmetrical depression deformity. **B:** Lorenz bar. **C:** Pectus excavatum bar inserted with thoracoscopic guidance. **D:** Immediate postoperative appearance. (Digital images provided by William Hardin, MD, University of Alabama, used with permission.)

Sternal Clefts

Congenital sternal clefts result from failure of midline fusion of the paired sternal bands. The cleft is usually in the superior portion of the sternum and may extend to but not include the xiphoid. The defects are rare and are usually repaired in the neonatal period when the chest is more pliable.^{22,32} The purpose of the correction is to protect the underlying mediastinal structures. After subcutaneous and substernal mobilization, the fibrocartilaginous sternal bars are approximated in the midline. If the cardiac structures are at risk, more elaborate repairs are required. Typically, the cleft is incomplete and

a V-shaped excision of the sternum at the most inferior aspect of the cleft may be required to avoid buckling of the sternum in that region.^{22,32} Cantrell pentology refers to a distal sternal cleft, omphalocele, diaphragmatic defect, pericardial defect, and intracardiac defect. Thoracic ectopia cordis (exstrophy of the heart) may occur as a part of this abnormality and this spectrum continues to have a high mortality.²²

Jeune Asphyxiating Thoracic Dystrophy

Jeune asphyxiating thoracic dystrophy is a rare developmental abnormality that results in the failure of chest wall growth. Traditional surgical procedures have involved sternotomies with placement of graft material to expand the chest. Most recently, the use of a vertical expandable prosthetic titanium rib (VEPTR) device allows division of the most posterior aspect of approximately the third to ninth ribs and division at the costochondral junction of the same ribs. The rib plate is then elevated to the curved VEPTR strut by wires, thus expanding the chest. This is done for both chests, and the device is serially expanded every 4 to 6 months to promote chest enlargement.^{22,33}

The “Slipping Rib” Syndrome

Slipping rib syndrome is an unusual cause for recurrent lower chest and upper abdominal pain. The cause is likely an inadequacy or rupture of interchondral fibrous attachments. The symptoms tend to be a popping or clicking sensation associated with pain. Pain is usually reproducible with palpation. Surgical therapy involves excision of the affected rib and cartilage relieving pain on the involved intercostal nerve.^{34,35}

“Flaring” of the Costal Margin

Patients are sometimes referred for surgical opinions regarding unusual prominence of the costal margin. The “flaring” is most pronounced when the patient is supine. This finding represents a variation of the normal development of the chest wall. Surgical correction should be avoided.

Costochondral “Tumor”

Prominence of a single costal cartilage may present as a concern of a tumor of cartilage or bone. This abnormality is usually found in preadolescents and adolescents. Patients may have undergone a diagnostic workup that includes chest radiographs, ultrasound, CT, or magnetic resonance imaging (MRI) prior to surgical consultation. This abnormality most likely represents a minor variation of a chest wall deformity, such as a pectus carinatum. The area of enlargement is rarely tender so that costochondritis is an unlikely explanation. Excision of the involved cartilage is rarely helpful. Plain radiographs or thoracic imaging are usually sufficient to exclude a tumor.³⁶

CONGENITAL LUNG LESIONS

Congenital lung lesions have been characterized as lesions of defective budding, differentiation and separation of the foregut, or more recently airway maldevelopment with resultant obstruction.^{37,38} These lesions include pulmonary sequestration (PS), congenital pulmonary airway malformation (CPAM), formerly CCAM, bronchogenic cyst (BC), and congenital lobar overinflation (CLO). The first three are in the family of bronchopulmonary foregut malformations. PS is characterized by aberrant blood supply, CPAM by hamartomatous lung parenchyma, and BC by an isolated cyst. There are overlaps between the elements so many lesions are found to be hybrid.^{37,38} CLO is likely a secondary response to abnormal compression or obstruction of a bronchus.

Pulmonary Sequestration

3 PSs are microscopic cystic masses of nonfunctioning pulmonary tissue without a normal bronchial communication with the tracheobronchial tree. In addition, these abnormalities receive blood supply from an aberrant systemic vessel usually from the descending aorta. The lesions are most commonly found in the lower lobes, more commonly on the left. They are characterized as intralobar or extralobar based on pleural lining.

Intralobar sequestrations are incorporated into the surrounding lung and are invested by its visceral pleura. They are most common in the left medial or posterior basal segment of the lower lobe. The arterial supply is from the descending aorta and the venous return is usually into a pulmonary vein.

Usually asymptomatic at birth, but aberrant air space connections can result in recurrent pneumonia.

Extralobar sequestrations occur outside of the pleura of the normal lung. They are most common in the lower left side of the chest but have been reported in a variety of locations including the retro peritoneum.³⁷⁻³⁹ In the retroperitoneum, they may be difficult to distinguish from neuroblastoma. These have occasionally been associated with congenital diaphragmatic hernia (CDH). In extralobar PS, in addition to systemic arterial supply, the venous return is systemic. In 20% of cases, the blood supply originates from the infradiaphragmatic aorta. These lesions can present with arteriovenous shunting which in rare cases can lead to high output heart failure.

Radiographic evaluation of PS involves chest radiographs, ultrasound and CT scans with contrast enhancement to identify the vascular supply. Intralobar sequestrations are treated with lobectomy. Extralobar sequestrations may be removed by excision of the sequestration. The lesions may be removed with thoracotomy or thoracoscopy with attention to safe ligation of the vascular supply (Fig. 102-3).³⁷⁻⁴²

Congenital Pulmonary Airway Malformations

4 CPAMs result from overgrowth of bronchial structures at the expense of the associated alveoli associated with an abnormal supplying airway affecting a single lobe in 95% of cases. This group of anomalies represents 30% to 40% of the developmental lung bud anomalies. On gross appearance, they can be solid, cystic, or both. The malformations have a normal blood supply and communicate with the normal tracheobronchial tree. The common classification separates these lesions into three main types. Type I CPAMs consist of cysts with large, irregular widely dispersed spaces larger than 2 cm or a single large cyst with multiple small surrounding cysts and represent 50% to 65% of postnatal cases. Type II CPAM is described as numerous smaller cysts (0.5 to 2 cm) and account for 10% to 40% of cases. Type III CPAMs are made of small cystic lesions (generally 0.2 cm) or solid lesions appearing similar to immature lung devoid of cartilage and make up of 5% to 10% of cases. CPAMs generally only affect one lobe but multilobar and bilateral involvement occurs. Most commonly, the lesions are left sided and affect the lower lobes. Several genes have been implicated in the development of CPAMs including HOXB5, Fgf7, and PDGF-B.⁴³

Figure 102-3. Pulmonary sequestration (PS). **A:** Sagittal ultrasound view of the aortic branch supplying an extralobar PS. **B:** Left-sided extralobar PS excised via a muscle-sparing thoracotomy. **C:** Intraoperative view of extralobar sequestration removed thoracoscopically. Note the main blood supply with clips.

Prenatal diagnosis is common occurring in 79% of cases. In fact, prenatal ultrasound has led to an increased diagnosis of lung lesions.⁴⁴ CPAMs may lead to sufficient pathophysiologic effects including life-threatening hydrops. Fetal surgery has included open resection and thoracoamniotic shunting with survival of some of the affected fetuses.^{36,42} The natural history of prenatally diagnosed CPAMs is variable and even large lesions may regress. Growth tends to plateau at 26 to 28 weeks gestation.^{43,44}

The incidence is reported to be between 1:25,000 and 1:35,000 live births which likely underrepresent the incidence as historically, approximately 14% of cases are stillborn. Although 80% are asymptomatic at birth, nearly 80% will have respiratory symptoms within the first month of life.³⁸ Less commonly, patients may present with pneumonia later in life (Fig. 102-4).

There is little controversy about symptomatic lesions which require resection of the involved lobe. Those with severe respiratory compromise may require resection on extracorporeal membrane oxygenation (ECMO) with excellent results. Other infants may benefit from an ex utero intrapartum treatment (EXIT) to ECMO approach when gas exchange is predicted to be compromised at delivery.⁴⁴ Treatment of asymptomatic lesions is controversial as the natural history of the lesion is unknown. There is concern for future infection and the possibility of malignancy.^{37,38,45,46} Those who recommend resection favor timing between 2 and 10 months of age. With antenatal diagnosis, a CT is necessary to determine resolution of the lesion. There is evidence of inflammation in the resected lesions leading to recommendation for early resection.⁴⁷ Lesions can be resected via thoracotomy or thoracoscopy. With multilobar and bilateral disease, CT scans assist in planning lung-preserving resections. Bilateral and multilobar lesions are thought to be associated with the development of pleuropulmonary blastoma.⁴⁶

Figure 102-4. Congenital cystic adenomatoid malformation (CCAM). **A:** Newborn chest x-ray of a patient with prenatal diagnosis of CCAM. Note that immediately after birth, the mass is fluid-filled and appears as a density in the right hemithorax. **B:** Chest x-ray of the same child at 5 months of age prior to surgical excision. Note the air-filled cystic appearance of CCAM. **C:** Transverse thoracic computerized tomographic view of CCAM.

Bronchogenic Cysts

BCs are uncommon anomalies arising from defective development of the large airways. They can be mediastinal or intrapulmonary and cause symptoms of cough as well as recurrent and chronic infection. These cysts appear as discrete masses and develop from the esophageal or tracheal position of the foregut. They are usually extrapulmonary and do not communicate with the normal tracheobronchial tree. Resection via thoracotomy or thoracoscopy is recommended due to the risk of bleeding, infection, or enlargement with compression of adjacent structures (Fig. 102-5).^{41,48-50}

Congenital Lobar Overinflation

CLO (previously labeled congenital lobar emphysema) is caused by abnormal development or compression of a lobar bronchus resulting in retention of fluid during fetal lung development and subsequent air trapping and overinflation after birth. The cause ranges from a deficiency of bronchial cartilage to compression from an extrinsic mass. The presentation is typically with upper lobe of either lung field and rarely multilobar. Definitive cause is rarely identified. Lobar overinflation may present as worsening respiratory distress caused by enlargement of the overinflated segment with compression of the normal surrounding lobe (Fig. 102-6). Symptomatic infants should undergo complete resection of the lobe. Care must be taken at resection as positive-pressure ventilation may worsen symptoms and require immediate thoracotomy. With relatively asymptomatic patients, symptoms will improve and allow for a nonoperative approach.^{39,51}

Diagnosis

Due to the routine use of prenatal ultrasound, many cystic lesions of the lung are now detected and followed prior to birth.^{37-39,44,46} Many of the patients with these lesions are asymptomatic in the perinatal period. Standard chest radiographs remain the standard for diagnosis and follow-up for lesions. Rapid thoracic CT scanning with contrast provides definitive mapping of the lesions including demonstration of aberrant vessels. Contrast esophagograms are indicated for children with dysphagia

and suspicion of connection with the GI tract. In lesions with suspected aberrant arterial supply, MRI angiography can be helpful if the CT is not definitive.

Treatment

There is controversy about the management of asymptomatic lesions with proponents of resection citing the rare association with malignant pulmonary neoplasms.³⁷⁻³⁹ Any cyst enlarging on serial radiographs should be resected due to the risk of respiratory compromise and the possibility of infection of the cyst and the surrounding tissue. The reason for long-term follow-up is the demonstration of progressive resolution.

Cysts of the Mediastinum

5 Benign cysts of the mediastinum are relatively common in the pediatric population. Most of these are relatively asymptomatic but surgery is recommended due to the possibility of enlargement with symptoms related to compression, hemorrhage, or infection. The symptoms which occur include cough, chest pain, stridor, hemoptysis, or dysphagia. The common lesions include thymic cysts, enterogenous cysts, lymphatic malformations (cystic hygromas), and pericardial cysts.

Figure 102-6. Congenital lobar overinflation. **A:** Chest radiograph demonstrating overinflation of the left upper lobe in an infant. Note the mediastinal shift. **B:** Operative photograph demonstrating an overexpanded left upper lobe decompressing through the incision.

Thymic Cysts

Thymic cysts present in the neck and mediastinum and are usually unilocular but may be multilocular. They are most commonly seen in the anterosuperior mediastinum. They are benign lesions with presence of cholesterol granulomas. Symptoms may arise from rapid expansion due to infection. Resection is recommended.^{52,53}

Enteric Duplication Cysts/Enterogenous Cysts

Enteric duplication cysts are usually located in the posterior mediastinum with microscopic evidence of double-layer smooth muscle and esophageal or gastric mucosa. They are from the same spectrum as bronchopulmonary cysts. These may communicate with the stomach or esophagus and may transverse the diaphragm. The cysts may also extend into the spinal canal.^{52,53} The lesions may have gastric mucosa leading to bleeding. Other symptoms may include airway compression or dysphagia (Fig. 102-7). Resection is indicated for all symptomatic lesions and is favored for asymptomatic lesions.

Lymphatic Malformations

Lymphatic malformations (cystic hygromas) are unilocular or multilocular cysts which are thin walled and derived from failure of adequate drainage of embryonic lymph sacs. These may occur in the head, neck, and mediastinum. The lesions insinuate around great vessels and nerves in the superior mediastinum. The incidence is 1 in 6,000 live births. Symptoms if present are related to enlargement (frequently due to hemorrhage) or infection. Resection while preserving vital structures is recommended although lesions have been treated with sclerotherapy. The most frequent complications are recurrence and accumulation of lymph in the resection bed.⁵²⁻⁵⁴

Pericardial Cysts

Pericardial cysts are asymptomatic and are found incidentally on chest radiograph. The cysts are found in the cardiophrenic sulcus as a discrete mass. The cysts are thin walled with a flat mesothelial lining and contain clear fluid. Resection can be performed with thoracotomy or thoracoscopy.^{52,54}

THORACIC TUMORS IN CHILDREN

6 Thoracic tumors are rare in children and diagnostic evaluation must exclude evaluation for both primary and metastatic conditions. Tumors may occur in the lung or the mediastinum.⁵⁴ Primary lung neoplasms in children are extremely rare.^{55,56} Metastatic lung lesions are more common in the pediatric population.⁵⁷ Mediastinal tumors reflect the nature of the section of the mediastinum in which they arise. Diagnostic evaluation begins with routine radiographs with CT scans and MRIs for further evaluation.⁵⁴

Metastatic Lung Tumors

7 Resection of metastases in the pediatric population has been proven to be beneficial for pediatric cancers. Eradication of the primary tumor and absence of other metastases are necessary for improvement in survival.⁵⁸ Resection is considered most frequently for osteogenic sarcoma, soft tissue sarcoma, and Wilms tumor.^{58,59}

Osteogenic Sarcoma

There is evidence that resection of metastases in osteogenic sarcoma improves survival if a complete resection can be performed. The factors which improve survival are ipsilateral involvement, smaller tumor size, and longer disease-free survival between diagnosis and occurrence of metastasis.⁵⁹ Metastases which are more peripheral have a better outcome compared with centrally located metastases.⁶⁰ In addition to metastectomy chemotherapy is required for elimination of micrometastatic disease. Metastases become calcified and therefore are palpable aiding with resection. There are some data that the outcomes are comparable between initial resection of metastases and resection of a second recurrence.⁵⁹ Improved survival is seen with tumor necrosis greater than 98% and disease-free interval of greater than 1 year. Mean survival after complete resection with aggressive resection is 33.6 months while mean survival without resection is 10.1 months.⁶¹ Thoracoscopy is felt to be inappropriate for this disease process since CT scans underestimate the number of lesions which can be palpated at thoracotomy.⁶² Bilateral lesions can be identified even when CT scans demonstrate only unilateral lesions leading some authors to recommend prophylactic contralateral thoracotomy. With bilateral involvement, in an appropriate population, simultaneous bilateral thoracotomy may lessen morbidity compared to the traditional staged thoracotomies.⁶³

Figure 102-7. Enterogenous cyst. This represents another abnormality in the spectrum of bronchopulmonary foregut malformations. **A:** Computerized tomography demonstrating a large mass occupying the right hemithorax. **B:** Surgical specimen.

Soft Tissue Sarcomas

Nonrhabdomyosarcomas such as synovial sarcoma respond poorly to chemotherapy and radiation therapy. In these tumors, complete resection of pulmonary metastases, but not debulking improves survival.⁶⁴ Lung metastasis in rhabdomyosarcoma responded to chemotherapeutic regimens but local treatment of the metastases did not improve survival.⁶⁵ Ewing sarcoma has a high rate of pulmonary metastases which have traditionally been treated with radiation therapy. More recent data suggest that metastectomy after irradiation leads to improved survival.⁶⁶ Delayed surgery after neoadjuvant therapy with resection of the chest wall lesion leads to decreased extent of excision and a higher rate of negative margins in tumors less than 8 cm.⁶⁷

Wilms Tumor

Pulmonary metastectomy in Wilms tumor is only indicated for persistent lesions after a 27-week regimen of chemotherapy and radiation therapy.⁶⁸ Thoracoscopy with resection of lesions is indicated

for diagnostic purposes. The outcomes demonstrate that there is improved 5-year survival for patients with CT-only metastases and that lung radiation in this group does not improve survival.⁶⁹

Primary Lung Tumors

Pediatric primary tumors are rare with comprehensive series documenting approximately 383 patients with primary malignant pulmonary neoplasm as of 1993 (Table 102-1). The majority of primary neoplasms are malignant but benign lesions also have significant morbidity due to location of the lesions. Operative exploration with total resection of all involved tissues is recommended.⁵⁶

Bronchial Adenomas

Bronchial adenomas are the most common of the malignant lung lesions (40%) in the pediatric population and include several different histologies including carcinoid tumor, mucoepidermoid carcinoma, and adenoid cystic carcinoma. Carcinoid is the most common malignant pulmonary lesion in the pediatric population and accounts for 85% of bronchial adenomas. Mucoepidermoid carcinomas account for 10% of the adenomas and originate from mucous glands in the submucosal and respiratory mucosa. They are centrally located. Adenoid cystic carcinoma comprises 5% of the bronchial adenomas and is described as a salivary gland-type tumor. Cough, pneumonitis, fever, respiratory distress, and hemoptysis are the most common presenting symptoms. Delay in diagnosis is common due to the nonspecific symptomatology. The disease is diagnosed with chest radiograph followed by CT scan. Bronchoscopy is required for diagnosis and biopsy can be performed but there is a high risk of hemorrhage. Treatment is by surgical resection which can include lobectomy, bilobectomy, pneumonectomy, or sleeve resection with regional lymphadenectomy. Intraoperative frozen section is useful to assure complete resection and to limit lung resection. Bronchial carcinoids do not usually present with carcinoid syndrome and presentation with the syndrome is a sign of extrapulmonary disease.⁵⁶

Table 102-1 Primary Pulmonary Neoplasms in Children

Type of Tumor	Number (%) ^a
Benign (n = 92)	
Inflammatory	48(52.2)
Hamartoma	22(23.9)
Neurogenic tumor	9(9.8)
Leiomyoma	6(6.5)
Mucous gland adenoma	3(3.3)
Myoblastoma	3(3.3)
Benign teratoma	1(1.1)
Malignant (n = 291)	
Bronchial "adenoma"	118(40.5)
Bronchogenic	49(16.8)
Pulmonary blastoma	45(15.5)
Fibrosarcoma	28(9.6)
Rhabdomyosarcoma	17(5.8)
Leiomyosarcoma	11(3.8)
Sarcoma	6(2.1)
Hemangiopericytoma	4(1.4)
Plasmacytoma	4(1.4)
Lymphoma	3(1.0)
Teratoma	3(1.0)
Mesenchymoma	2(0.7)
Myxosarcoma	1(0.3)

^a“(%)” is percent of benign or percent of malignant tumors.
Modified from Hancock et al.⁷³

Bronchogenic Carcinoma

Bronchogenic carcinoma is the second most common malignant pulmonary cancer. Bronchogenic carcinoma consists of adenocarcinoma and undifferentiated carcinomas in the pediatric population. These tumors have been associated with CPAMs but have been reported in normal lung as well.^{56,70}

Human papilloma virus has been associated with the squamous cell variant. Resection with ipsilateral lymphadenectomy is the treatment of choice. Prognosis for bronchogenic carcinoma is poor as the presentation tends to be with advanced stages. Symptoms are related to metastases with bone pain or tumor burden with weight loss.⁵⁶

Pleuropulmonary Blastoma

Pleuropulmonary blastoma is the third most frequent lung tumor in children and is most common in children under 4 years of age.^{56,71,72} The lesion consists of mesenchymal elements and embryonal stroma without epithelial neoplasia. The tumor is known to be part of the spectrum of tumors related to the mutation of the DICER1 gene.⁷¹ The tumor usually presents peripherally. These tumors are associated with CPAMs. There are three types; type I consisting of multilocular cysts, type II consisting of a combination of cystic and solid components, and type III having proliferating mesenchyme without cysts.⁷² Treatment is with resection and adjuvant chemotherapy. Survival in type I has been reported at 91% while type II/III have survivals of 43%.⁷¹

Figure 102-8. Lung neoplasm in an 8-year-old child: inflammatory pseudotumor. **A:** Presenting chest radiograph with right lung collapse. **B:** Biopsy of an obstructing endobronchial mass demonstrates inflammatory pseudotumor (inflammatory myofibroblastic tumor). **C:** Computerized tomographic “virtual bronchoscopy” image after initial biopsy demonstrates deformation of the right main stem bronchus and carina due to tumor infiltration. **D:** Computerized tomography reconstruction of the external appearance of airways demonstrating the deformation of the carina and right main stem bronchus. The child underwent excision of the right main stem bronchus and carina and tracheobronchial reconstruction. **E:** Postoperative transverse thoracic computerized tomography at the level of the reconstruction of the carina.

Other Malignant Tumors

Sarcomas, including fibrosarcoma, rhabdomyosarcoma, and leiomyosarcoma are the next most common

primary malignant lung neoplasm in children. They may arise endobronchially or peripherally. These have been reported to arise in documented cystic disease.⁷³ Inflammatory pseudotumor is considered to be the most common “benign” tumor in children. The tumor is a myofibroblastic spindle cell soft tissue tumor with infiltrative plasma cells, lymphocytes, and eosinophils. Recently these have been classified as intermediary lesions with a molecular rearrangement involving the tyrosine kinase receptor anaplastic lymphoma kinase. Symptoms are nonspecific such as fever, chest pain, cough, and recurrent pneumonias.⁷⁴ These may present as an endobronchial lesion but are more often peripherally located. The lesion may invade local structures and be aggressive locally and may recur locally but spontaneous regression has been reported. Complete resection is recommended as no adjuvant regimen has gained widespread acceptance. Nonsteroidal anti-inflammatory agents have been utilized with some success (Fig. 102-8).

Hamartoma

Hamartomas are lung nodules composed of cartilage and gland-like formations in an irregular and haphazard orientation. They grow slowly and are the most common benign lesion in adults but the second most common in children.⁵⁶ Radiographically, they have a “popcorn” calcification in 10% to 25% of cases. The majority are located in the periphery of the lung. Conservative surgical resection is recommended. These may be associated with gastric smooth muscle tumors and extra-adrenal paragangliomas (Carney triad) in adolescent females; and in this age group, a workup should be performed to exclude these diagnoses.

Mediastinal Tumors

Mediastinal tumors in the pediatric population can be benign or malignant with 37% of lesions being malignant in children.⁵³ Tumors have a predilection for arising from the different components of the mediastinum. Neurogenic tumors are the most common mediastinal tumors in the pediatric population.⁵⁴ These tumors arise in the posterior mediastinum from the sympathetic ganglia, the intercostal nerves, and paraganglia cells.⁵³ These may grow very large before detection and may manifest with Horner syndrome or opsoclonus–myoclonus syndrome. The neurogenic tumors may be malignant (neuroblastoma, ganglioneuroblastoma) or benign (schwannoma, ganglioneuroma, or neurofibroma).^{54,75,76} Neuroblastoma originating in the mediastinum has a better prognosis than in other sites. These tumors have more favorable biology and lower rates of N-myc amplification as well as improved rates of event-free and overall survival.⁷⁷ Diagnosis is by CT and MRI with MRI allowing improved assessment of extension into the spinal foramina.^{78,79} Tumors may be resected by a thoroscopic approach or via thoracotomy Figure 102-9.^{80,81}

Neurofibromas and schwannomas arise from intercostal nerves of sympathetic nerves. The schwannomas are encapsulated without nerve fibers within the tissue. Neurofibromas are unencapsulated, have nerve fibers running through the mass and are common in patients with neurofibromatosis.⁸² Isolated tumors may be removed but tumors associated with neurofibromatosis tend to extend over nerve sheaths precluding complete removal. These are associated with malignant degeneration.

Lymphomas arise in the anterior and middle mediastinum and are the most common anterior mediastinal mass in children.⁷⁹ These are usually inhomogeneous and resection is not required. Both Hodgkin and non-Hodgkin lymphoma arise in the mediastinum. Diagnostic workup involves biopsy for tissue diagnosis as the diagnosis often requires tissue subtyping.⁵⁴ Due to risk of airway compromise, the most accessible tissue, such as supraclavicular lymph nodes, should be biopsied and special care is required for biopsy of the mediastinum including partial upright positioning, spontaneous ventilation, availability of rigid bronchoscope, and avoidance of muscle relaxants. Risk of airway compromise is increased in patients with greater than 50% reduction in tracheal cross-sectional area, or those with dyspnea and orthopnea. Treatment is with chemotherapy.

Figure 102-9. A: Large neural tumor in coronal view CT scan with calcifications (neuroblastoma). B: Same mass on transverse view.

Teratomas are the most common mediastinal germ cell tumor and are composed of all three germinal cell layers.^{53,79} These lesions are benign, usually cystic and encapsulated. They frequently contain calcification on radiography (Fig. 102-10). Most are asymptomatic but may present with respiratory distress. Presenting symptoms can include stridor, tachypnea, and severe respiratory distress especially when lying supine.⁸² The cysts frequently contain mature ectodermal elements such as hair, skin, and neuroglial elements and may contain bone, teeth, and fat. The tumors may be large and tend to displace rather than invade surrounding tissue.⁷⁹ Workup includes preoperative measurement of α -fetoprotein and β -HCG. Resection is the treatment of choice and confirms the diagnosis. Treatment of mature teratomas is resection. Immature teratomas which contain malignant elements are treated with chemotherapy and radiation in addition to surgery.

Figure 102-10. Mediastinal teratoma. A: Transverse thoracic computerized tomography of a large anterior mediastinal teratoma

Other mediastinal tumors are very rare but often require surgical biopsy or extirpation. These include neurolemmoma, pheochromocytoma germ cell tumors, rhabdomyosarcomas, and thymic tumors.

Chest Wall Tumors

Ewing sarcoma, chondrosarcoma, and liposarcoma are malignant tumors which may arise from the chest wall. Local resection may require extensive chest wall excision and prosthetic reconstruction.⁸³ Primitive neurectodermal tumors are malignant small cell tumors carrying a poor prognosis. Improvement in survival is accomplished with multimodal therapy which includes chemotherapy, radiation, and surgery with aggressive management of pulmonary metastases.^{66,67,83}

Respiratory Papillomatosis

Recurrent respiratory papillomatosis is caused by neoplastic proliferation associated with acquisition of papillomavirus during delivery. It is usually confined to the larynx and upper tracheal airway with spread in less than 1% of cases. Treatment is with laser ablation and may require multiple treatments. Prognosis is poor due to the recurrence of the disease.⁷⁸

ESOPHAGEAL ATRESIA/TRACHEOESOPHAGEAL FISTULA

8 The first description of the classic proximal esophageal atresia with distal fistula was by Thomas Gibson in 1697. The first description of esophageal atresia was by Durston in 1670 who found a blind esophageal pouch in one pair of thoracopagus conjoined twins.⁸⁴ Initial attempts at repair or palliation were unsuccessful. Leven and Ladd reported survivors but only after staged reconstruction. The first successful primary repair was reported by Dr. Cameron Haight in 1941.^{85,86} Outcomes have improved related to refinements in surgical technique and postoperative care.^{84,87-91} In the modern era, survival is related to the degree of prematurity and the presence of cardiac disease.

Embryology

The development of the human respiratory system begins as a folding of the flat endodermal layer into the primitive gut tube. The respiratory system is derived from the foregut endoderm with the appearance of the laryngo-tracheal groove in the ventral floor just caudal to the level of the pharynx. Despite intense study, the precise events in morphogenesis are not well understood. There are two theories, one of which suggests that the respiratory system develops as a rapid outgrowth from the original foregut tube. This theory is consistent with the accepted pattern of rapid longitudinal growth at the distal ends of the bronchopulmonary structures. Other theories support the fusion of the lateral foregut walls resulting in the separation of the trachea from the esophagus.^{92,93} The third theory based on studies of chick embryos supports the development of three folds, anterocranial (laryngeal), dorsal (pharyngoesophageal), and inferior (tracheoesophageal). The paired laryngeal and single tracheoesophageal folds appear first defining the tracheoesophageal space. Subsequently continued movement of the folds results in the definition of the separate trachea and esophagus. At the same time the pharyngoesophageal fold defines the boundary of the pharynx and esophagus.

One theory of the development of tracheoesophageal fistula is caused by failure of tracheal growth. A second theory is that there is failure of the active separation process. Another theory is the abnormal movement of the pharyngoesophageal fold leading to failure of division. Sonic hedgehog has been implicated in the development of esophageal atresia/tracheoesophageal fistula based on adriamycin-induced malformations in rats.

Classification

Descriptive terminology is used to indicate the anatomic configuration of a patient with esophageal atresia. The most common type of lesion is a proximal atresia with a distal tracheoesophageal fistula which accounts for 76% to 85% of all cases in recent series.^{87,88,90,91,94} Esophageal atresia without fistula occurs in approximately 3% to 17% and TEF without fistula in 4% to 6% of cases. Proximal fistula and both proximal and distal fistula occur in approximately 1% of cases each. Initially alphabetic classification schemes were devised and the most common variety of esophageal atresia/tracheoesophageal fistula is still commonly referred to as “Gross type C” (Fig. 102-11).

Incidence and Epidemiology

Esophageal atresia is relatively common occurring in 1:2,500 to 1:4,500 live births. There is a slight preponderance of males.^{84,91,94} Chromosomal anomalies, congenital heart disease, and other anomalies are more common than expected.

Figure 102-11. The anatomy of the variants of esophageal atresia and tracheoesophageal fistula (TEF). **A:** Proximal pouch with distal TEF (most common type occurring in 85% of patients; Gross type "C"). **B:** Esophageal atresia without TEF (5%). **C:** TEF without esophageal atresia (<5%). **D:** Esophageal atresia with proximal and distal TEF (rare). **E:** Proximal TEF and distal pouch (rare).

Clinical Findings, Diagnosis, and Pathophysiology

Diagnosis of esophageal atresia is suspected with a history of choking with feeding and is confirmed by the inability to pass an NG tube into the stomach. Excessive drooling may be noted. Maternal polyhydramnios should raise suspicion for the diagnosis. If not diagnosed early, respiratory distress and aspiration may occur. Confirmation of the diagnosis is with radiograph identifying a tube in a proximal pouch in most cases. Occasionally injection of air to outline the pouch will be necessary for confirmation. Presence of a scaphoid abdomen with no intragastric air on radiograph taken several hours after birth confirms the diagnosis of pure esophageal atresia.⁹⁶ Reflux of gastric contents through the fistula can enter the lungs which becomes more problematic in the face of respiratory compromise and is less of an issue with spontaneous ventilation. In cases of severe respiratory distress, gastrostomy or

gastrostomy plus division of fistula become an emergency procedure.

Associated Anomalies

Associated anomalies are present in approximately one-half of the neonates with esophageal atresia. The most common associated anomalies are cardiovascular defects which occur in 17% to 50% of infants. Genitourinary, other gastrointestinal, skeletal neurologic, and craniofacial defects are also found. The occurrence of vertebral anomalies, anorectal malformations, cardiac, tracheoesophageal renal, and limb (usually radial) anomalies is known as the VACTERL association. Two or more of the defects must occur to be denoted as VACTERL and this occurs in 10% to 21% of cases.

Preoperative Management

Attempts at feeding are discontinued and sump tube is placed in the upper esophageal pouch. Precautions such as head-up position are advocated to decrease reflux via the fistula into the lung. Intubation is avoided as it increases the risk of reflux into the lungs via the fistula. Ventilatory support is more likely to be needed for low birth weight or prematurity. Preoperative antibiotics are given in the majority of patients.⁹⁷ Emergent bedside gastric decompression may be necessary before definitive surgery. If gastrostomy decompression does not improve ventilation, emergency operative ligation or placing an occluding distal esophageal balloon may allow for ventilation.⁹⁸

In addition to chest radiograph, echocardiography is performed to determine the side of the aortic arch as well as to evaluate for major cardiac anomalies. In patients with a right-sided arch, the operative approach is modified.⁹⁹ Radiographs of the spine are also commonly performed.

In an attempt to stratify infants into groups to determine outcomes, Waterston developed criteria based on birthweight, pneumonia, and associated anomalies. With improvements in neonatal critical care, the criteria have been revised to with the current Spitz classification which uses a 1,500 g weight as the cutoff, with or without major cardiac disease. Currently survival for greater than 1,500 g infants without cardiac disease is approximately 97%, survival for either cardiac disease or less than 1,500 g approaches 82% and for both birth weight less than 1,500 g and cardiac anomaly survival is approximately 50%.⁹⁰

Surgical Technique

In most patients, gastrostomy is unnecessary and the technique is a posterolateral right extrapleural thoracotomy (Fig. 102-12). There is no need to divide the serratus or the latissimus muscles. A more posterior approach through the auscultatory triangle affords excellent exposure. The extrapleural plane is established at the fourth intercostal space and developed sufficiently to allow control of the fistula and mobilization of the proximal pouch. Initially, the fistula is divided and ligated followed by mobilization of the proximal pouch. Anastomosis is performed in a single layer with an absorbable suture, more recently using a monofilament. If needed there are various techniques for elongation and the esophagus may be mobilized both proximally and distally. Myotomies on the upper pouch, either circular or spiral and flap tubularization have been described. A transesophageal tube is often passed during the case and can be utilized for feeding prior to performance of a postoperative esophagogram.¹⁰⁰

Figure 102-12. A: Schematic illustration of esophageal atresia with distal tracheoesophageal fistula. B: The initial management of this anomaly includes upright or prone posture, sump suction of the blind esophageal pouch. C: The right extrapleural operative approach. After division and closure of the fistula, primary esophagoesophagostomy is performed.

High-risk infants who cannot safely undergo surgical correction of their esophageal abnormality may be treated with delayed repair. A decompressive gastrostomy, proximal pouch suctioning, and parenteral nutrition are used until the infant is ready for operation. Severe respiratory failure (usually from prematurity) and structural heart disease are the most common reasons to delay esophageal surgery. A staged repair that employs gastrostomy, surgical division of the tracheoesophageal fistula, followed by esophageal anastomosis as a second thoracic operation is rarely used except as a lifesaving approach.

In the case of pure esophageal atresia without fistula, a prolonged period before definitive repair may be used to improve the likelihood of completing a primary repair. A feeding gastrostomy is the initial operative management and may be technically challenging due to microgastria. Using bouginage the ends of the esophagus are elongated and once the ends are close, a thoracotomy is performed to repair the esophagus (Fig. 102-13). Other methods of elongation have been described with staged repair using traction sutures in the upper and lower esophagus (Fig. 102-14). Daily tensioning results in lengthening of the esophagus over a few weeks.⁹⁵ Alternatively, extrathoracic elongation may be utilized.^{101,102}

Figure 102-13. Patient with pure esophageal atresia treated initially with feeding gastrostomy, and proximal pouch stretching. This “gap-o-gram” demonstrates close approximation of a dilator in the proximal pouch and a probe placed in the distal esophagus via the gastrostomy. The child subsequently underwent primary repair of the esophagus.

Figure 102-14. In patients with ultra-long-gap esophageal atresia, traction sutures are placed on the upper pouch and lower segment. Tension is increased daily until the segments lengthen, allowing primary repair.

Esophageal replacement is reserved for the worst cases of long-gap atresia, pure atresia or failed initial operations. The esophagus may be replaced later using stomach, gastric tube, or colon. These cases may be temporized with spit fistula and sham feeds.

Tracheoesophageal fistula with esophageal atresia is referred to as H-type fistula. The orientation is such that the opening into the trachea is always proximal to the esophageal entry site. Repair is performed via a cervical approach after bronchoscopically stenting the fistula with a small catheter. The catheter aids in dissection and care must be taken to stay in the plane of the esophagus.

Thoracoscopic approaches to the repair of esophageal atresia have been described with results demonstrating equivalent outcomes to open repair.^{103,104} Thoracoscopic techniques for esophageal lengthening in long-gap atresia have also been described.¹⁰⁵

Results, Complications, and Outcomes

Technical mishaps may occur during the procedure when anatomy is misidentified or dissection is carried out improperly. Injury to the vagus nerves, recurrent laryngeal nerves, posterior trachea, and adjacent vessels must be avoided.

Anastomotic leak occurs in approximately 10% to 20% of cases and most may be treated nonoperatively. The presence of a leak prolongs hospitalization.¹⁰⁶ When detected, the retropleural tube is left in place, the infant is not fed, and antibiotics are administered. Repeat contrast radiographs are employed to document healing prior to initiation of oral feeds.

Esophageal stricture is seen in up to 40% of infants after repair. These usually respond to a few sessions of dilation performed in the operating room with endoscopic and fluoroscopic assistance as necessary to assure the safe traverse of dilators or placement of balloon dilators.¹⁰⁷ More recalcitrant strictures require more frequent dilation sessions, medical and/or surgical control of gastroesophageal reflux, and occasionally reoperation with stricture resection and reanastomosis.

Recurrent tracheoesophageal stricture is reported in up to 10% of patients. These may respond to endoscopic ablation, a construct placed into the fistula or may require operative division placing tissue between the esophagus and trachea to separate the suture lines.¹⁰⁸

Gastroesophageal reflux is present in nearly all patients with esophageal atresia but is asymptomatic in many. When symptomatic, it may lead to respiratory symptoms and stricture formation. Medical management with thickened feeds, acid reduction, and prokinetics is the first line of therapy. Refractory reflux may require surgical control of reflux.

Esophageal dysmotility is present in the majority of patients and may be responsible for dysphagia and recurrent respiratory problems.

Tracheomalacia occurs in approximately 10% of patients and may be diagnosed after the repair of esophageal atresia. On bronchoscopy, the trachea appears oval in shape rather than round and the anterior and posterior walls coapt during the respiratory cycle. The trachea appears to fish-mouth in the anteroposterior dimensions during spontaneous expiration. Patients may develop tracheomalacia “fits” when agitated and the condition may deteriorate with complete inspiratory block and unconsciousness. Intubation and resuscitation may be required. The symptoms are completely relieved by intubation. Patients with less severe symptoms may improve over time as the trachea grows. Severe symptoms require either tracheostomy or a tracheal suspension with an aortopexy under bronchoscopic guidance. It may be difficult to determine whether the symptoms are from gastroesophageal reflux or tracheomalacia and sometimes both an antireflux procedure and a tracheomalacia procedure may be required.¹⁰⁹

Long-term results have improved and most children can look forward to normal existence. Although growth may be slow in the first 5 years of life, by 20 years of age less than one-third of the children have heights or weights below the 25th percentile.¹¹⁰ Mortality remains high for infants with severe congenital heart defects and chromosomal anomalies. Late deaths may occur related to respiratory disease (tracheomalacia, reactive airway disease, gastroesophageal reflux, and aspiration). Adult survivors of esophageal atresia repair have a normal quality of life with the exception of morbidity from esophageal, functional, and respiratory disorders.¹¹¹ The very long-term effects are unknown but Barrett esophagus and esophagitis have been reported¹¹² but the incidence is low and further studies are required to determine the need for long-term surveillance.

OTHER CONGENITAL ANOMALIES OF THE TRACHEA AND ESOPHAGUS

Laryngotracheoesophageal Cleft

Laryngotracheoesophageal clefts are rare anomalies resulting from the failure of normal separation of the esophagus and trachea. These are the most severe anomalies and the presence of the common aerodigestive channel plus the association of gastroesophageal reflux leads to aspiration with respiratory damage and a high mortality rate. The lesions are classified by the length of the common channel. Type I clefts involve the supraglottic larynx. Type II defects extend beyond the carina to the cervical trachea. Type III clefts involve the entire trachea and type IV defects extend onto one or both bronchi. Type III and IV clefts are frequently associated with other anomalies such as esophageal atresia, microgastria, and congenital heart disease.

Type I clefts may be repaired via an endoscopic or translaryngeal approach and do not require tracheostomy. Type II clefts require cervical exposure either laterally or via the anterior wall of the larynx and trachea. The anterior approach provides good exposure and decreases the risk of damage to neurovascular structures. The approach to type III and IV defects is via a right thoracotomy and a right neck incision. However reports of midline exposure have been described. The common channel is divided and repaired with interrupted sutures with tracheostomy.¹¹³ Oromotor function and chronic aspiration are problems and most children require gastrostomy and many require operative control of gastroesophageal reflux.

Congenital Esophageal Stenosis

Congenital esophageal stenosis is a rare condition. The stenosis is frequently within 2 cm of the gastroesophageal junction. The true incidence is unknown but is report to be 1:25,000 to 1:50,000 live births. The narrowing of the lumen is present at birth but may not present with clinical symptoms immediately. There are three histologic subtypes: ectopic tracheobronchial remnants, segmental fibromuscular hypertrophy, and a membranous diaphragm or stenosis. These have been associated with esophageal atresia. Symptoms may only occur when solids are started. Diagnosis is by esophagograms. CT scans may confirm the diagnosis. Esophagoscopy confirms the diagnosis. Initial management is esophageal dilation. If the stenosis is due to respiratory tract remnants, need for surgery is more common. Surgery consists of resection of the stenotic segment with end-to-end anastomosis.¹¹⁴

Esophageal Duplication

Esophageal duplications are found in the posterior mediastinum and are covered by a muscular wall. Most of these are attached to the wall of the esophagus and are covered by smooth muscle. Approximately 10% communicate with the lumen of the esophagus. Neurenteric cysts communicate with the spinal canal. Although many are asymptomatic, they may present with airway or esophageal compression. In older children and adults, the presentation may be dysphagia, retrosternal pain, and epigastric discomfort. There are reports of bleeding from acid dyspepsia. Excision is recommended which may be accomplished by thoracotomy or thoracoscopy (Fig. 102-15).^{53,54}

Vascular Rings

Vascular rings are a set of congenital defects in which the trachea or esophagus are encircled and compressed by vascular structures. These account for approximately 1% of all congenital cardiovascular anomalies. These rings may lead to tracheal narrowing with associated tracheomalacia. Symptoms may include stridor, respiratory distress, or dysphagia. Barium swallow may be suggestive of the lesion. CT scan and MRI are utilized to demonstrate the anomaly. Echocardiography is performed to rule out structural cardiac anomalies. Bronchoscopy may also be useful to determine the degree of tracheal narrowing. The most common type of abnormality is the double aortic arch resulting from persistence of both the right and left embryologic aortic arches. The ascending aorta bifurcates, surrounding the trachea and esophagus. Other causes of complete or incomplete rings include pulmonary artery sling and aberrant right subclavian artery. When the vascular ring is symptomatic, the patient should be treated by the appropriate division of the ring and lysis of the fibrous bands surrounding the trachea and esophagus.¹¹⁵

Figure 102-15. Thoracoscopic excision of an esophageal duplication cyst in a patient presenting with dysphagia. Video endoscopic view of the left superior hemithorax. (+) indicates site of original esophageal duplication cyst. Light from the intraesophageal endoscope can be seen. Arrows demonstrate the subclavian artery. The mass (*) is nearly excised.

Congenital Tracheal Stenosis

Congenital tracheal stenosis represents a spectrum of obstructive lesions most commonly treated with operative repair. The etiologies include complete tracheal rings, compression from anomalous cardiovascular anatomy, and tracheomalacia. Short stenosis may respond to resection and anastomosis.

Longer lengths of stenosis can be managed by patch tracheoplasty and slide tracheoplasty. Use of cardiopulmonary bypass during repair may improve outcomes. In a review article outcomes were similar with the use of slide tracheoplasty and patch tracheoplasty.^{116,117}

FOREIGN BODIES OF THE TRACHEOBRONCHIAL TREE

9 Foreign-body aspiration occurs commonly in infants and young children and is a potentially life-threatening event. A report in 2001 found that nonfood choking was a cause of death for 449 persons under the age of 14 with 65% of the deaths in children under 3 over a 20-year period. Choking on food causes death of approximately 75 children per year. Management is with the Hopkins rod lens system with fiberoptic illumination utilized with rigid pediatric bronchoscopes and specialized grasping devices allows for safe and reliable extraction of foreign bodies.¹¹⁸⁻¹²⁰

Pathophysiology

Complete airway obstruction can occur at the level of the pharynx, hypopharynx, or trachea. Back blows, abdominal thrust, or the Heimlich maneuver may dislodge the obstruction and save a life. An inhaled foreign body which reaches the bronchial level may cause a ball-valve phenomenon allowing bi-directional but unequal flow of air. Air trapping and hyperinflation of the affected lobe lead to mediastinal shift. Complete blockage results in loss of volume due to atelectasis.

Foods are the most common aspirated items and include peanuts, carrots, popcorn, hotdogs, and grapes. Coins and toys are the most common nonfood items aspirated.

Clinical Presentation

Most affected children are less than 3 years of age. History of choking crisis is present in the majority of children. Other symptoms include cough, wheezing, dyspnea, and fever. The most common signs are unilateral decreased breath sounds, unilateral wheezing, and rhonchi.

Management

Chest radiographs, including bilateral lateral decubitus films are performed unless the patient is in respiratory distress. The films may demonstrate hyperinflation or failure to develop atelectasis on the affected side. In addition, the films may show pneumonia or atelectasis with a completely occluding foreign body.

Bronchoscopic evaluation and foreign-body removal is performed in the operating room under general anesthesia. The rigid bronchoscope with optical forceps can be used to retrieve most aspirated foreign bodies (Fig. 102-16). Flexible graspers, Fogarty balloon catheters, and baskets can be useful especially if the foreign body has migrated distally or has a smooth or round surface. Fluoroscopic assistance can be useful with radiopaque objects which have migrated into the peripheral airways.

Over time, pneumonia or atelectasis may develop and a foreign body presenting with chronic lung infection will require surgical resection of the associated portion of the lung.

CONGENITAL ABNORMALITIES OF THE DIAPHRAGM

10 Developmental defects of the diaphragm have surgical implications. Advances in management of neonatal respiratory failure, fetal surgery, and lung developmental biology have arisen from the clinical and laboratory evaluation of CDH (CDH, Bochdalek, or posterolateral hernia). CDH, which is relatively rare, occurring in 1 in 3,000 neonates has led to a significant amount of clinical and basic science research.

Figure 102-16. Schematic illustration of a peanut foreign body being extracted from the right main stem bronchus under direct vision.

In 1754, McCauley described the clinical course and postmortem anatomy of an infant with CDH.¹²¹ Although Bochdalek's¹²² understanding of the embryology of CDH was incorrect, this congenital defect continues to carry his name. Prior to 1940, the successful repair of this defect remained rare.¹²³ In 1946, Gross¹²⁴ reported the postoperative survival of an infant less than 24 hours of age. From that time until the 1980s the standard of care was emergent operative repair. At that time, CDH was considered to be an anatomic derangement treated by an anatomic correction (the thought was that by getting the bowel out of the chest, the lung compression would improve and the outcome would improve).

Until the 1980s, emergency surgery was considered the primary therapeutic goal based on mechanical concept of providing space for growth of lungs. The overall published survival rates in the 1980s were 50% with ranges from 20% to 70% based on case selection. In the late 1980s, there was a switch in management from emergency surgery to stabilization.¹²⁵ Management in the postnatal period is directed at decreasing pulmonary hypertension while maintaining adequate oxygen saturations (between 85% and 95% preductal).^{125,126} Surgical repair is deferred until after physiologic stabilization and this has led to improved survival of infant with CDH. Further improvements in therapies for pulmonary hypertension and method to increase lung growth to combat pulmonary hypoplasia should result in improvement in the survival and decreased morbidity of CDH infants.

Embryology of the Diaphragm

Mammalian lung development occurs in vivo as a coordinated developmental process that includes (a) airway and acinar development, (b) cellular differentiation, (c) biochemical maturation, (d) interstitial development including vasculature and extracellular matrix, and (e) physical growth or enlargement. These parallel developmental processes occur in such a fashion that at any one time during development, there are characteristic relationships among each component that define the so-called stages of lung development.¹²⁷⁻¹²⁹ Hormones such as the glucocorticoids, thyroid hormone, and retinoic acid have been shown to regulate several of the crucial cellular interactions required for proper pulmonary organogenesis and differentiation. In the human embryo, respiratory tract development begins in the fourth week of gestation as a ventral out pouching of the foregut that soon has bifurcated and begun branching into the surrounding mesenchyme. The primitive, pluripotent epithelial cells differentiate into both bronchial and alveolar cell lines, under the control of the surrounding mesenchyme. By a process of asymmetric branching, the divisions are complete by the 16th week of gestation. Lung at this phase has columnar epithelium with thick mesenchyme giving rise to the descriptive term *pseudoglandular phase of development* because of its histologic appearance. The canalicular phase that follows and continues up to about the 24th gestational week is characterized by flattening of the epithelium of the distal airways, thinning of the mesenchyme, and the growth of the capillary network that surrounds the terminal airways. Gas exchange becomes functionally possible at the end of this phase. The terminal sac period that follows refers to the appearance of a thin respiratory

epithelium in apposition to a capillary network capable of supporting gas exchange. True alveolar formation in humans begins shortly before or around the time of birth. Alveolar maturation and multiplication takes place after birth and may continue up to 8 years of age.

The precursors of the mesoderm-derived diaphragm begin to form during the fourth week of gestation with the appearance of the peritoneal folds from lateral mesenchymal tissue. At the same time, the septum transversum forms from the inferior portion of the pericardial cavity and serves to delineate the thoracic from the abdominal cavities. Eventually, the septum transversum leads to the formation of the central tendinous area of the fully developed diaphragm. The pleuroperitoneal folds extend from the lateral body wall and grow medially and ventrally until they fuse with the septum transversum and dorsal mesentery of the esophagus during the sixth gestational week. Complete closure of the canal takes place during the eighth week of gestation, with the right side closing before the left.¹³⁰ Muscularization of the diaphragm appears to develop from the innermost layer of thoracic mesoderm, although other mechanisms have been proposed.¹³¹ Nitrofen-induced diaphragmatic hernias in rats have been studied with scanning electron microscopy. Normal diaphragmatic development includes the development of the pleuroperitoneal fold which connects to the mesonephric ridge and transverse septum. The lung buds protrude into the peritoneal cavity and come in close contact with the liver on the right and the stomach on the left. The lungs follow the enlarging pleural cavities and the peritoneal portion becomes smaller. A trapezoidal structure forms laterally and is defined as the posthepatic mesenchymal plate (PHMP). The PHMP grows rapidly in a laterodorsal direction and forms the prominent ridge covering part of the liver. The opening closes from a continuous ingrowth of the PHMP.¹³² In diaphragmatic hernia development, the PHMP is smaller and malformed although the pleuroperitoneal fold and the transverse septum appear normal. This leaves part of the liver uncovered and can bulge into the thorax. The lung development proceeds normally until the liver and lung approach each other and lung hypoplasia is related to the degree of herniation (Fig. 102-17).¹³²

Congenital Diaphragmatic Hernia Pathology and Pathophysiology

CDH occurs in 1:3,000 to 2:4,000 live births. Approximately one-third of antenatally diagnosed infants with CDH are stillborn, with most of the deaths subscribed to other fatal anomalies. Defects are more common on the left side based on the CDH registry.¹³³ CDH represents a sporadic developmental anomaly with some familial cases reported. One-third of patients have associated major defects. CDH associated with an abnormal karyotype or cardiac defect is associated with a poor outcome.¹³⁴

Figure 102-17. Anatomy of the diaphragm showing the location of congenital diaphragmatic defects.

The cause of CDH is unknown but is presumed that some combination of intrinsic predisposition (genetic factors) and environmental factors (teratogen or deficiency) results in abnormal diaphragm and lung development.¹³⁵ A nitrofen-induced model of CDH also inhibits retinal dehydrogenase leading to decreased retinoic acid, which has also been found in human infants with CDH.

During the early development of the diaphragm, the midgut is largely extracoelomic. If closure of the pleuroperitoneal canal has not occurred by the time the midgut returns to the abdomen during the 9th and 10th weeks of gestation, the abdominal viscera herniate through the lumbocostal trigone into the

ipsilateral thoracic cavity. The resulting abnormal position of the bowel prevents its normal counterclockwise rotation and fixation. No hernia sac is present if the event occurs before complete closure of the pleuroperitoneal canal, but a nonmuscularized membrane forms a hernia sac in 10% to 15% of CDH patients. In addition to the small bowel, other intraabdominal organs such as the spleen, stomach, colon, and liver may also herniate through the diaphragmatic defect.

Left-sided CDH is characterized by a 2- to 4-cm posterolateral defect in the diaphragm through which the abdominal viscera have translocated into the ipsilateral thoracic cavity. On a right-sided defect, the large right lobe of the liver can occupy most of the hemithorax. The hepatic veins may drain ectopically into the right atrium, and the liver and lung may be fused.¹³⁵

The pathophysiology of CDH has been attributed to pulmonary parenchymal compression by the herniated organs and its effect on growth and maturation of the lung. An emerging school of thought attributes the pulmonary hypoplasia to an early mesenchymal developmental insult to the lung and diaphragm. Unilateral diaphragmatic hernia is associated with both ipsilateral and contralateral abnormal pulmonary development, although hypoplasia is more severe on the ipsilateral side. The lung on the side of the hernia is much smaller than its contralateral counterpart, and both are strikingly smaller than normal lungs (Fig. 102-18). The pulmonary vascular disease associated with CDH is characterized by abnormal pulmonary vascular development, abnormal vasoreactivity, and a disorganization of postnatal vascular remodeling. There are fewer capillaries which are unevenly distributed. Both the media and the adventitia have structural abnormalities consistent with increased muscularization in utero. Sonic hedgehog signaling which is involved in the development of respiratory bronchioles is delayed in CDH. Levels of several regulatory proteins are changed compared to controls but no causative relationship has been demonstrated.^{136,137}

Pulmonary blood flow accounts for only 7% of cardiac output during normal fetal development. Pulmonary vascular resistance is high. The fetus preferentially shunts oxygenated blood from the placenta through the foramen ovale and ductus arteriosus in a right-to-left direction into the systemic circulation. With the institution of breathing at birth, oxygen levels rise causing pulmonary vascular resistance to fall, which in turn allows an increase in pulmonary blood flow. Increased arterial oxygen tension then also induces spontaneous closure of the ductus arteriosus. Persistent fetal circulation may develop if this process is interrupted. Elevated pulmonary vascular resistance results in right-to-left shunting of blood at either the atrial or ductal levels with the delivery of unsaturated blood into the systemic circulation. As shunting increases, the oxygen saturation in the systemic circulation falls. The resulting hypoxia further increases pulmonary vascular resistance and compromises pulmonary blood flow while increasing the right-to-left shunt flow. Factors that contribute to the persistence of high pulmonary vascular resistance in CDH lungs are thought to be the structural changes of decreased total arteriolar cross-sectional area in the involved lungs and the increased muscularization of the arterial structures that are present. Additional exacerbations of pulmonary vascular resistance may be induced by the known stimulators of pulmonary hypertension, which include hypoxia, acidosis, hypothermia, and stress. Alternations in the levels of prostaglandins, leukotrienes, catecholamines, and the renin angiotensin system had been implicated as mediators of this complex process. The combination of hypoplastic lungs and lungs prone toward increased vascular resistance often proves to be deadly; a vicious cycle may ensue in which hypoplastic lungs and associated hypoxia leads to pulmonary hypertension in a lung vasculature already prone toward reactive vasospasm. The increase in pulmonary pressures results in a greater shunt, which in turn further reduces oxygen levels.

Figure 102-18. Autopsy specimen of an infant with severe pulmonary hypoplasia secondary to congenital diaphragmatic hernia. Pulmonary hypoplasia is bilateral, but the left lung is most severely affected.

Diagnosis

Diagnosis of CDH is often made on prenatal ultrasound examination and a recent population-based study demonstrated that 66% were diagnosed prenatally.¹³⁸ In addition to the defect, polyhydramnios is common. Prenatal MRI is utilized for more accurate delineation of the defect.¹²⁵ Postnatal presentation frequently includes cyanosis and respiratory distress shortly after birth in severely affected neonates. On physical examination, the patients have a scaphoid abdomen. A plain chest radiograph with loops of intestine in the chest confirms the diagnosis of CDH with an ng tube in place to confirm the position of the stomach (Fig. 102-19). After confirmation of diagnosis, echocardiography should be performed to evaluate for degree of pulmonary hypertension and to determine presence of cardiac defects. Differential diagnosis includes eventration of the diaphragm, anterior diaphragmatic hernia (Morgagni), congenital pulmonary malformations, unilateral pulmonary effusion, and primary agenesis of the lung.¹³⁹

Figure 102-19. A: Chest radiograph of a newborn with a left congenital diaphragmatic hernia. Mediastinal structures are shifted to the right. Abdominal viscera occupy the left hemithorax. The nasogastric tube locates the stomach. The child underwent repair of the congenital diaphragmatic hernia after treatment and resolution of pulmonary hypertension. B: Immediate postoperative photograph demonstrates hypoplastic lung, flattening of diaphragm, and return of abdominal viscera to normal position.

Prognostic Factors

Multiple tools for prognosis of CDH have not been successful. One method for evaluation is the lung to head ratio (LHR) which is determined by multiplying the simultaneous sonographic measurements of the size of the contralateral lung in an anteroposterior and lateromedial direction, and dividing by the head circumference. Ratios less than 1 have been associated with poor outcome. Because the LHR increases with age, the percent of predicted value for gestational age has been used with no survivors below 15% of predicted.¹⁴⁰ Liver above the diaphragm has also been used to determine outcome with decreased survival with liver-up. The combination of a low LHR with liver-up has a poor outcome. The size of the defect was a significant factor in survival, a major cardiac anomaly and 1-minute Apgar scores of ≤ 4 were associated with increased mortality.^{141,142} Physiologic parameters have been used to develop calculations for prediction of survival including the CDHSG which utilizes birthweight and 5-minute Apgar, the CNN (Canadian Neonatal Network) equation utilizing SNAP-II scores and gestational age, and the WHSR_{PF} using blood gas values in first 24 hours, with the CDHSG having the best predictive value.¹³⁸

Treatment

At the time of antenatal diagnosis, the mother and fetus should be referred to an appropriate tertiary care perinatal center with the availability of the full array of respiratory care strategies.

Resuscitation should begin with standard neonatal resuscitation guidelines and then proceed with endotracheal intubation and nasogastric tube insertion. Bag-valve mask should be avoided. Careful management of temperature regulation, glucose homeostasis, and volume status should be performed. Fluid resuscitation should be performed with crystalloid, blood products, and colloid. Inotropes such as dopamine or dobutamine are utilized if needed. Most infants can be managed with simple pressure-cycled ventilation with a goal of maintaining a preductal PaO₂ greater than 60 correlating with saturation between 85% and 95%. Keeping peak pressures below 25 and accepting CO₂ between 45 and 65 decreases barotrauma. For failure of gentle ventilation, the next step in therapy would be the use of jet ventilator or oscillator ventilator; use of HFOV with mean airway pressure 13 to 17, frequency of 10 Hz, and amplitude of 30 to 50 keeping the contralateral lung expansion at 8 ribs.¹²⁶

In addition to ventilatory methods, a variety of agents are utilized to modify pulmonary vascular resistance. Inhaled nitric oxide has been used in infants with approximately 30% responding. Studies have demonstrated that the results are temporary and NO should be considered a temporizing measure. Phosphodiesterase-5 inhibition with sildenafil has a vasodilatory effect but can also cause systemic hypotension worsening the shunting. In addition, the absorption is variable so dose-effect relationship is not well understood. Milrinone, a phosphodiesterase-3 inhibitor improves right ventricular function and relaxes pulmonary vessels but there is no evidence to support or discourage the use of milrinone. Recent studies have demonstrated the use of prostacyclin or prostaglandin E1 to decrease pulmonary artery pressure and pulmonary vascular resistance. Inhalation of prostacyclin seems to be preferable to IV usage. Other medications such as tyrosine kinase inhibitors and endothelin receptor antagonists may show promise.¹³⁶

Surfactant has been demonstrated to be reduced in CDH infants. However, surfactant has not been demonstrated to improve survival.¹⁴³

Failure to improve with ventilatory and pulmonary hypertension management strategies should prompt consideration of ECMO. ECMO can be used for an extended period of time when ventilator therapy has failed. Indication for the use of ECMO is the failure to improve in the setting of severe pulmonary hypertension. In recent years the use of ECMO has decreased but still ranges from 15% to 40% of diaphragmatic hernias; with survival following ECMO of 51%.¹²⁵

Surgery

Delayed surgery has been demonstrated to improve survival in some studies. Current consensus is that the repair should be done in a semielective manner.

The diaphragm defect is usually approached through a subcostal incision, although the repair can be performed through a thoracotomy incision (Fig. 102-20). Both thoracoscopic and laparoscopic approaches have been described. The abdominal organs are returned to the abdomen. The defect in the diaphragm is repaired. Primary repair with nonabsorbable suture is preferred. If the defect cannot be repaired primarily due to size, a prosthetic patch such as Goretex has been utilized. The major drawback of the use of a patch, either inert or bioactive is recurrent herniation which may occur in up to 50% of

infants.¹⁴⁴ There may have been loss of intraabdominal domain and difficulty with closing the abdomen. In these cases, a silo may be used.¹⁴⁵ Tube thoracostomy is used at the surgeon preference. A recent meta-analysis of minimally invasive versus open repairs demonstrated that recurrence rate is higher after MIS and operative time is longer.¹⁴⁶ Postoperative ventilator time and postoperative mortality were higher after open surgery but none of the studies were randomized and this may have represented selection bias.¹⁴⁶

Figure 102-20. Repair of a congenital diaphragmatic hernia (CDH). **A:** Operative appearance of CDH. **B:** Placement of sutures for repair of a typical left posterolateral diaphragmatic defect. **C:** Completed repair. **D:** Prosthetic material may be used for large defects to avoid tension.

Postoperative management should continue the goals set before surgery. Continued attention to fluid status is important in the postoperative period. Weaning from the ventilator should be slow and deliberate. Refractory postoperative pulmonary hypertension is relatively common in those who required ECMO and is often treated with iNO and prostacyclin in conjunction with frequent echocardiography.

Outcome

Survival rates have been reported at 65% to 78% in the last decade improved from 50% in the past. As survival has improved, other morbidities have been demonstrated including long-term use of bronchodilators, need for gastrostomy for nutritional support, and increased rate of GERD requiring surgery. Musculoskeletal deformities also occur with scoliosis, pectus excavatum, pectus carinatum, and chest wall asymmetry described.¹⁴⁷ Adult survivors of CDH have demonstrated higher incidence of GERD, recurrent intestinal obstruction, and recurrent abdominal pain. Scores in the Gastrointestinal Quality of Life Index are similar to controls while there were lower scores in the Health-related Quality of Life Survey but most still had good or satisfactory scores.¹⁴⁸

Evolving Therapies

Open fetal repair of diaphragmatic hernia has been performed but there was no survival benefit and

there was an increase in preterm delivery so this is not currently offered. Tracheal occlusion in utero has been developed as a strategy based on observations that the lungs of neonates with congenital high airway obstruction developed hyperplastic lungs. Fetal tracheal occlusion improved lung volume but there was still impairment in the lung. Fetal endoscopic tracheal occlusion has been trialed with fewer premature deliveries. In the US trial there was no improvement in survival in a randomized trial. The European trials add a second fetal surgery to remove the balloon to allow for improvement in the development and function of type II pneumocytes and to increase surfactant production. With the European trial, vaginal delivery is possible but with the US trial, the infants were delivered by EXIT procedure, using the placenta to maintain oxygenation until an airway is secured.¹⁴⁰

Foramen of Morgagni Hernia

The anterior CDH is rare and accounts for 3% to 5% of all CDHs. It is commonly diagnosed during childhood. It is frequently diagnosed from chest or abdominal radiographs being performed for presumed pneumonia or gastrointestinal symptoms (Fig. 102-21).¹⁴⁹ This is an anteromedial hernia at the junction of the septum transversum and the thoracic wall with contents being seen in a retrosternal position. There is a hernia sac present and the sac may contain colon, small intestine, or liver. The hernias are repaired due to the risk of segmental intestinal volvulus or obstruction. Repair may be performed through a laparoscopic approach. The sac is excised and the diaphragm is sutured to the undersurface of the posterior rectus sheath at the costal margin. Laparoscopy has been demonstrated to be an effective method for repair of this type of hernia.^{150,151}

Figure 102-21. Morgagni hernia. (A) Anteroposterior and (B), lateral radiographs of patient with Morgagni hernia.

Eventration of the Diaphragm

Eventration of the diaphragm is diagnosed by the abnormal elevation of one or both hemidiaphragms and can be congenital or acquired. The congenital form may appear very similar to a diaphragmatic hernia with a sac. The cause of the congenital form is unknown although infectious causes have been implicated. The acquired form is a consequence of injury to the phrenic nerve. Small children are more likely to be affected than older children as the decreased chest size leads to dyspnea and respiratory infection. Surgery is utilized for symptomatic cases after several months of observation if symptoms are minimal. The surgical management is with plication of the diaphragm with nonabsorbable sutures. The repair may be performed through the abdomen or the chest and both thoroscopic and laparoscopic techniques are applicable.¹⁵²

Diaphragmatic Pacing

Ventilator-dependent children with spinal cord injury or central hypoventilation syndromes may benefit from diaphragm pacing.¹⁵³ The application of repetitive stimulus patterns to the phrenic nerves causes rhythmic contractions of the diaphragm. Phrenic nerve pacing wires are implanted at the cervical or intrathoracic level. Receivers are implanted in subcutaneous pockets, while an external microprocessor-controlled transmitter/antenna assembly activates the receiver. Patients with injured phrenic nerves (high spinal cord injury) may benefit from diaphragm pacing after intercostal-to-phrenic nerve transfer.¹⁵⁴

PLEURAL DISEASES

Empyema

Empyema is the accumulation of purulent material in the pleural space. In children, empyema is most often the sequelae of bacterial pneumonia. Empyema develops when a parapneumonic effusion becomes infected or when a necrotizing pneumonia erodes into the pleural space. Empyema may also be caused by penetrating thoracic trauma, intrathoracic, or cervical esophageal perforation or as a complication from surgery on the chest. The American Thoracic Society divides the empyema process into 3 stages:

1. Exudative: Thin free-flowing fluid with a low cell count.
2. Fibrinopurulent: Frank pus is present and fibrin formation begins to cover the pleura with development of loculations.
3. Organizing: Thick peel with fibroblasts.¹⁵⁵

The most common organism responsible for empyema is *Streptococcus pneumonia* despite the utilization of pneumococcal vaccinations. Other common organisms are *Staphylococcus aureus* and *Hemophilus influenza*.¹⁵⁶ The signs and symptoms include worsening pneumonia with fever, tachypnea, dyspnea, and sometimes cyanosis. Abdominal pain may be present. Chest radiograph demonstrates the presence of fluid and loculation. CT imaging is the best method of determining the extent of loculated fluid versus underlying pulmonary pathology (Fig. 102-22).

Figure 102-22. Video-assisted thoracoscopic treatment of complicated empyema in children. **A:** Chest radiograph of a 2-year-old child presenting with pneumonia and pleural effusion. **B:** Computerized tomography demonstrates complicated pneumonia with loculated empyema. **C:** Video endoscopic view of organized empyema debris. **D:** “Decortication” procedure includes removal of all loculated, organized debris from the hemithorax. All surfaces of the visceral and parietal pleura are accessible using video endoscopic techniques. **E:** Immediate postoperative chest x-ray shows the expected residual parenchymal lung disease. **F:** One month later, the chest radiograph findings have resolved.

With a small amount of fluid, the empyema may resolve with antibiotics alone. When the collection becomes larger, the treatment is drainage of the collection. Several trials have compared fibrinolytics to video-assisted thoracoscopy (VATS). Both VATS and chest tube with fibrinolytics have been shown to be

effective with a systematic review demonstrating no superiority of VATS.¹⁵⁷ Other studies have demonstrated improvement after VATS.^{158,159}

Pneumothorax

Spontaneous pneumothorax is relatively uncommon. The etiology seems to be lung connective tissue changes predisposing to leaks into the pleural space. This occurs in approximately 2.6 per 100,000 population of children requiring hospitalization in the United States in 2000. It has been suggested that blebs are associated with the disease. The presentation is usually with chest pain and shortness of breath but may also be associated with cough. The pain may be pleuritic in nature. Diagnosis is best confirmed with chest radiograph.¹⁶⁰ Chest CT has been utilized for identification of blebs but a negative examination does not predict freedom from recurrence.¹⁶¹

Treatment of pneumothorax depends on the patient. Observation with or without high flow oxygen is appropriate for the relatively asymptomatic patient. Chest tube placement is the next stage of treatment. For recurrent pneumothoraces, intrapleural sclerosing agents such as talc can be used. VATS with bleb resection and pleurodesis has also been described with good results.¹⁶²

Chylothorax

Chylothorax which is the accumulation of chyle in the pleural space is a rare cause of effusion in children but is the most common cause of effusion in the neonate.¹⁶³ Chylothorax is associated with pulmonary lymphangiomas and lymphangiectasia. Chylothorax may also be a manifestation of Down, Turner, and Noonan syndromes. Chylothorax may occur due to trauma to the thoracic duct either iatrogenic or noniatrogenic due to blunt trauma. Malignancy and granulomatous diseases may cause obstruction of the thoracic duct leading to chylothorax.

The initial symptoms are related to accumulation of fluid in the pleural space with dyspnea, cough, and chest discomfort. Pleuritic pain and fever are rare. Diagnosis is by chest radiograph combined with findings on thoracentesis. The fluid is usually milky in appearance with triglycerides greater than 1.1 mmol/L, total cell count greater than 1,000 cells per microliter, and lymphocyte predominance greater than 80%.¹⁶⁴

Management consists of expansion of the lung with thoracentesis or tube thoracostomy. Minimization of lymph flow is managed by either parenteral nutrition or diet manipulation using only dietary medium-chain fatty acids. Long-term, this can lead to life-threatening immunologic problems. Surgical management is then employed. Thoracic duct ligation can be performed either via thoracotomy or thoracoscopic approach. This may require the administration of cream via a nasogastric tube in the hours before surgery. If this fails, pleurectomy and pleurodesis or pleuroperitoneal shunting may be employed.

Chapter 103

Pediatric Abdomen

Thomas T. Sato and Marjorie J. Arca

Key Points

- 1 Gastroschisis occurs with an incidence rate of 1 in 2,000 live births and is characterized by exposed intestine herniating through a defect to the right of the umbilicus. In contrast, omphalocele is a midline abdominal wall defect characterized by herniated visceral contents contained within the umbilical cord covering and has a high incidence rate of associated congenital anomalies.
 - 2 A congenital, indirect inguinal hernia is an abnormal, patent continuation of the peritoneum through the internal inguinal ring; inguinal hernia repair is the most common elective procedure in pediatric surgery.
 - 3 Neonatal bilious emesis should be considered the result of an acute mechanical intestinal obstruction until proven otherwise; emergent surgical evaluation is warranted to determine whether intestinal malrotation with midgut volvulus is present.
 - 4 Necrotizing enterocolitis (NEC) is a progressive, inflammatory intestinal condition of the surviving premature neonate. Perforated NEC is the most common neonatal surgical emergency.
 - 5 Hirschsprung disease is caused by aganglionosis of the myenteric nervous system in the rectum. Most commonly, the rectosigmoid colon is involved, but the length of contiguous aganglionosis varies in length proximally. Both propulsion and reflexive relaxation may be disordered or absent in the rectum, leading to functional bowel obstruction in the neonate and chronic constipation in the older child or adolescent. Enterocolitis associated with Hirschsprung disease is a potentially life-threatening condition.
 - 6 Intussusception is the invagination or telescoping of a proximal segment of intestine into an adjacent distal segment and is the most common cause of intestinal obstruction in infants and children 3 months to 3 years of age.
 - 7 The incidence of biliary atresia is 1 in 8,000 to 12,000 live births and is the most common cause of chronic cholestasis in infants and children as well as the most frequent indication for pediatric liver transplantation. Early diagnosis and management is necessary for optimal outcome.
-

ABDOMINAL WALL DEFECTS

Gastroschisis

1 Gastroschisis occurs with an incidence of about 1 in 2,000 to 4,000 live births. Infants with gastroschisis tend to be born to mothers who are younger (teenage), white, and consumed alcohol or tobacco during pregnancy.¹⁻³ Familial cases of gastroschisis are distinctly rare.⁴ Associated congenital anomalies are uncommon. However, in about 10% of cases, intestinal atresia or stenosis can be seen and is thought to be a result of mechanical or vascular compromise to the herniated bowel. Rarely, infants with gastroschisis have complete loss of small bowel secondary to volvulus in utero.

The pathophysiology of gastroschisis remains unknown. In normal fetal development, two umbilical veins are initially present. As the intestine returns to the abdominal cavity through the umbilicus, the right umbilical vein undergoes resorption, leaving the left umbilical vein intact. Weakness of the umbilical membrane at the site of umbilical vein resorption may allow the evisceration of the intestine through the defect. This explanation is consistent with the clinical observation that the gastroschisis defect is almost always located to the right of the umbilicus. Routine antenatal ultrasonography has documented the sequential development of gastroschisis as a consequence of a ruptured hernia of the umbilical cord in utero.⁵ Therefore, gastroschisis should be considered an isolated mechanical defect of the developing umbilical cord rather than a global defect in embryogenesis.

The amount of bowel eviscerated in gastroschisis can be extensive because the bowel has not

undergone complete mesenteric rotation and fixation at this particular time in embryogenesis. The bowel may be thickened and the mesentery may be foreshortened secondary to the inflammatory response induced by direct exposure to amniotic fluid. In gastroschisis, herniation of the liver is distinctly unusual (Fig. 103-1).

Omphalocele

Anatomy, Embryology, and Pathophysiology

The incidence rate of omphalocele is approximately 1 in 6,000 to 10,000 live births and has been stable over the past several decades. *Omphalocele* is a midline abdominal wall defect of varying size characterized by the presence of herniated visceral contents into the translucent sac of the umbilicus. The sac is composed of amniotic membrane, mesenchymal tissue known as *Wharton jelly*, and peritoneum. The umbilical cord attaches to the sac and may be eccentric in origin (Fig. 103-2). The sac may be inadvertently ruptured before or during delivery but it is always present. Similar to gastroschisis, intestinal malrotation is usually present. Unlike gastroschisis, the bowel is typically normal in appearance because it has not been directly exposed to the amniotic fluid. Small omphaloceles are defined as 2 to 3 cm in diameter and have only a small amount of herniated bowel within the sac. Closure of small omphaloceles is typically performed without significant physiological complications. In contrast, giant omphaloceles defined as greater than 4 cm in diameter can lead to extensive herniation of the stomach, bowel, liver, and spleen with subsequent underdevelopment of the abdominal cavity (Fig. 103-3).

Omphalocele results from incomplete closure of the anterior abdominal wall at the umbilicus during embryogenesis. During week 4 of gestation, the midgut undergoes progressive elongation in the yolk sac outside the embryonic coelomic cavity. The midgut returns to the abdominal cavity during week 10, where it undergoes normal rotation and fixation of the mesentery to the posterior abdominal wall. Normal closure of the anterior abdominal wall requires return of the midgut to the abdominal cavity, along with growth and fusion of the anterior body folds (cephalic, caudal, and two lateral) at the base of the umbilicus. Failure of growth, migration, or fusion of the lateral body folds leads to omphalocele. Failure of growth and fusion of the cephalic folds may lead to either a supraumbilical omphalocele associated with a midline sternal defect (Fig. 103-4) and a herniated heart, termed *ectopia cordis*, or a constellation of defects known as the *pentalogy of Cantrell*.⁶ This sequence includes a sternal cleft, an absence of the septum transversum of the diaphragm, a pericardial defect, a cardiac defect, and an epigastric omphalocele. Infants born with either *ectopia cordis* or *pentalogy of Cantrell* have significant morbidity and often, these conditions are lethal.

Figure 103-1. Gastroschisis. The defect is to the right of the normal umbilicus, and the bowel is thickened and inflamed.

Associated anomalies are more common in infants with omphalocele than with gastroschisis, reflecting the more global abnormality of embryogenesis in omphalocele. About 50% to 60% of infants with omphalocele have at least one associated congenital anomaly involving the skeleton, gastrointestinal tract, nervous system, genitourinary system, and cardiopulmonary system.^{7,8} In addition, infants with omphalocele have a higher incidence of chromosomal abnormalities and other conditions such as Beckwith–Wiedemann syndrome. A comparison of gastroschisis and omphalocele is summarized in Table 103-1.

Figure 103-2. Omphalocele. The herniated intestines and liver are visible inside the sac. The umbilical cord attaches to the sac.

Figure 103-3. Ruptured omphalocele. Although the bowel is relatively normal in appearance, the abdominal cavity is extremely underdeveloped.

Perioperative Management for Gastroschisis and Omphalocele

In contemporary practice, infants with gastroschisis can be safely delivered vaginally.^{8,9} Studies comparing vaginal delivery with elective cesarean section for infants with gastroschisis demonstrated no significant differences in outcome.^{10,11} Early delivery to minimize intestinal damage in gastroschisis patients has not been proved to be efficacious.^{12,13} Fetal well-being has been advocated to be the primary determinant for gastroschisis. To prevent birth-related hepatic injury, cesarean section is preferable for prenatally diagnosed infants with giant omphaloceles.

After delivery, infants with either gastroschisis or omphalocele have similar initial management priorities. If necessary, an adequate airway with effective ventilation and oxygenation is established. The infant should be maintained under either an external warmer or a humidified incubator. An orogastric sump tube should be inserted early and placed on suction to prevent further intestinal distention. In gastroschisis, the herniated viscera should be examined to make certain that the mesentery is not twisted. In addition, the tightness of the opening of the abdominal wall should be assessed to ensure that there is sufficient perfusion of the bowel. The viscera should be covered with gauze plastic wrap to prevent further contamination, hypothermia, and volume depletion. Alternatively, the infant's entire lower torso can be placed inside a plastic bowel bag. Regardless of the method, the initial therapeutic goal is to provide rapid, effective temporary coverage of the viscera. Adequate support of the herniated viscera must be provided to prevent intestinal ischemia. This can be done by placing the baby on his or her side, and placing support under the intestines. With large omphaloceles, the position of the infant's liver and viscera may impair venous return from the inferior vena cava when the infant is supine, and these infants may preferentially require a left-side-down position to maintain normal hemodynamics. Intravenous dextrose and broad-spectrum antibiotics are administered. Infants with gastroschisis will have higher intravenous fluid requirements to maintain euvolemia. If the infant is not delivered at a center where definitive surgical care can be provided, urgent transport should be arranged.

Figure 103-4. Operative exploration of giant omphalocele with abdominal wall defect, absence of the septum transversum of the diaphragm, pericardial defect, and cardiac defect.

DIAGNOSIS

Table 103-1 Comparison of Gastroschisis and Omphalocele

Characteristic	Gastroschisis	Omphalocele
Defect size (diameter)	2–3 cm	2–15 cm
Sac	Never	Always, may be ruptured
Gestational age	Prematurity	Term
Umbilical cord	Adjacent (left side) of defect	Attached to sac
Herniated viscera	Small bowel, stomach, colon	Small bowel, stomach, colon, liver
Malrotation	Yes	Yes
Bowel character	Inflammatory, edematous	Normal
Enteral nutrition	Delayed	Normal
Associated anomalies	Uncommon (10% atresia)	Common (50%)

Gastroschisis. Once the infant with gastroschisis has been stabilized, measures are taken to secure the viscera and, if possible, correct the abdominal wall defect. One option is to take the infant to the operating room, where reduction of the herniated viscera with primary fascial closure of the abdominal wall is an achievable goal in approximately 60% to 70% of infants with either gastroschisis. Gentle but definitive stretching of the abdominal wall is performed, and proximal decompression of the bowel is maintained with orogastric decompression. The defect may need to be enlarged to evaluate the intestinal tract fully and/or reduce the viscera into the abdominal cavity. The limiting factor in primary closure of a congenital abdominal wall defect is the increased intra-abdominal pressure generated by the reduction of the herniated viscera. Increased intra-abdominal pressure can lead to abdominal compartment syndrome. Features of neonatal abdominal compartment syndrome include impaired venous return caused by compression of the inferior vena cava, reduction of splanchnic blood flow leading to mesenteric ischemia, and respiratory compromise secondary to impaired diaphragmatic excursion. Intraoperative measurement of intragastric or intravesical pressure, end-tidal CO₂, central venous pressure, or regional oximetry may be helpful in determining the safety of primary abdominal wall closure. If the herniated viscera cannot be reduced primarily, the viscera is placed in a constructed Silastic pouch or performed silo. Daily partial reduction of the viscera within the silo is performed. This technique allows gradual reduction of the herniated viscera into the abdominal cavity, and complete reduction is usually obtained within 3 to 7 days. The infant is returned to the operating room for removal of the temporary silo with delayed primary closure of the abdominal wall defect (Fig. 103-5). Alternatively, a large abdominal wall defect may be effectively covered with abdominal skin flaps, with delayed repair of the ventral hernia months to years later (gross closure).

In some centers, all babies with gastroschisis are managed by placing a preformed silo at the bedside after the baby is born. Thereafter, the viscera is slowly reduced into the abdomen and eventual fascial closure is attained.¹⁴ Some studies caution that this practice may lead to longer ventilator and fluid requirements.^{14,15} Another method that has been described in gastroschisis patients with noninflamed pliable intestines is to reduce the viscera with some sedation at the bedside, fold the umbilical cord stump over the skin closure, and place a pressure dressing over the defect.¹⁶ The use of the umbilical stump has been described even for patients requiring staged or silo closure.¹⁷ This method of closure has been shown to effect fewer days of mechanical ventilation in retrospective studies.¹⁷⁻²⁰

Omphaloceles. Given the high incidence of associated anomalies, infants with omphalocele should undergo diagnostic investigation, guided by the clinical presentation and physical examination. These studies include chest radiography, echocardiogram, and renal ultrasound, in addition to baseline blood work. Chromosomal analysis may be necessary. Until the decision is made with respect to the timing and method of repair, the omphalocele should remain covered and protected with a gauze dressing. If the omphalocele is ruptured or torn, immediate closure or coverage is necessary.

Figure 103-5. Silastic chimney or silo for temporary coverage and staged reduction of giant omphalocele.

Closure of omphaloceles is dictated by the size of the defect, the amount of viscera extruded into the sac, and the abdominal domain. There is no standard definition of what constitutes a regular versus a giant omphalocele. Practically, a giant omphalocele has an abdominal wall defect larger than 4 cm, containing a portion of liver, and is difficult to close primarily in the first days of life without physiologic compromise.

Omphaloceles with a small abdominal wall defect typically would have operative fascial closure with sac excision in the newborn period. Many techniques have been described to close giant omphaloceles including sac excision and temporary coverage with grafts, use of intraperitoneal tissue expanders,^{21,22} and allowing the omphalocele sac to scar and then epithelialize in the latter technique.

The sac can be physically supported and left undisturbed, allowing epithelialization of the sac over several weeks to months. Antibiotic solutions or ointments are usually applied to control desiccation.^{22–25} Delayed repair of the ventral hernia is required. This delay is particularly useful in the infant with a giant omphalocele and a small, underdeveloped abdominal cavity that prohibits primary closure.

Infants with repaired omphalocele usually have relatively prompt return of bowel function after definitive repair. In comparison, nearly all infants with gastroschisis have delayed intestinal function following closure. The use of total parenteral nutrition (TPN) is essential in the treatment of these infants because it allows nutritional support while the bowel inflammatory process resolves. It is not unusual for these infants to require up to 4 weeks after repair to have bowel function normalize, and time taken to achieve full enteral feeding is not affected by the use of erythromycin as a prokinetic agent.²⁶ Approximately 15% of infants with gastroschisis develop necrotizing enterocolitis (NEC), a diffuse, often life-threatening inflammatory complication of the neonatal intestinal tract.²⁷ In addition, infants with gastroschisis are at risk for nutrient malabsorption and intestinal dysmotility with inability to tolerate full enteral feeding. In particular, infants with gastroschisis and associated intestinal atresia may have pronounced intestinal dysmotility and may require long-term, sometimes lifelong, dependence on TPN for caloric intake.²⁸

Long-term outcome of infants operated on for gastroschisis or omphalocele is usually dependent on the morbidity and mortality of associated conditions rather than the abdominal wall defect itself. Surgical conditions such as undescended testicles, Meckel diverticulum, and adhesive small bowel obstruction are encountered with moderate frequency. Adhesive small bowel obstruction most commonly occurs in the first-year of life and requires operative management in the majority.²⁹ Most children with repaired abdominal wall defects enjoy satisfactory health and quality of life, although they have been reported to have a lower degree of physical fitness measured by exercise time and maximal oxygen consumption.³⁰

Umbilical Hernia

Anatomy and Embryology

Congenital umbilical hernia is the most common abdominal wall defect in infants and children. The umbilical ring begins to contract circumferentially after birth and normally is reinforced by the paired lateral umbilical ligaments (the obliterated umbilical arteries), the singular round ligament (the obliterated umbilical vein), the urachal remnant, and the transversalis fascia. Incomplete growth or impaired development of any one of these structures can lead to weakness at the umbilical ring and cause a congenital umbilical hernia.

Clinical Issues and Management

Congenital umbilical hernias generally do not pose significant problems during childhood. Rarely, an umbilical hernia presents with incarceration of intra-abdominal contents within the sac.³¹ Infants and children may also present with infection or drainage at the umbilicus from associated urachal or vitelline duct remnants. The incidence rate of congenital umbilical hernia has been reported to be 25% to 50% in black infants and 4% to 9% in white infants in the first few months of life.³² There is an increased incidence of umbilical hernia in premature infants, and there is a tendency for familial inheritance.

Diagnosis of umbilical hernia is usually made after separation of the umbilical cord remnant from the umbilicus and is often initially noted by parents or pediatrician. The size of the defect may vary from a few millimeters to several centimeters and is typically reducible and asymptomatic. Age and size of the defect are the most important factors determining spontaneous closure rates.³³ Many umbilical hernias spontaneously close within the first 2 to 3 years of life. Parents should be reassured that complications related to untreated umbilical hernia are rare. Given the high rate of spontaneous closure and the relatively asymptomatic nature of most umbilical hernias, operative repair is generally not performed during the first 2 years of life. Skin ulceration or an episode of incarceration should prompt earlier repair. Large defects with significant protrusion may necessitate surgery, and parents may desire repair if an older child appears to be self-conscious about the hernia.

Nearly all umbilical hernia repairs can be performed as outpatient surgical procedures. An incision is made along the umbilicus and the hernia sac is dissected free circumferentially. The sac is completely excised and primary fascial closure is performed. The umbilical skin is typically preserved and sutured to the fascial closure, and an acceptable cosmetic result is almost always achievable. Large umbilical hernias with redundant skin may require umbilicoplasty. The incidence of complications such as wound infection and recurrence is low.

Inguinal Hernia and Hydrocele

Anatomy, Embryology, and Pathophysiology

2 Inguinal hernias constitute one of the major surgical problems of infancy and childhood. Inguinal hernia repair is the most common elective general surgical procedure performed by pediatric surgeons. Three distinct anatomic types of inguinal hernias are observed in children: congenital indirect (99% of infants and children), direct (0.5%), and femoral (<0.5%). An *indirect inguinal hernia* is an abnormal, patent continuation of the peritoneum through the internal inguinal ring. The hernia sac originates lateral to the deep inferior epigastric vessels and descends along the spermatic cord within the cremasteric fascia. The sac can reside completely within the inguinal canal or descend through the external inguinal ring into the scrotum. A *direct inguinal hernia* originates medial to the deep inferior epigastric vessels and is external to the cremasteric fascia. The hernia sac protrudes directly through the posterior wall of the inguinal canal and can descend through the external inguinal ring and into the scrotum. A *femoral hernia* originates medial to the femoral vein and descends inferior to the inguinal ligament along the femoral canal. A femoral hernia never enters the scrotum or the labia.

The developing testicle is initially adjacent to the mesonephros and subsequently descends to the scrotum during the third trimester of gestation. The peritoneal extension that descends alongside the chorda gubernaculum of the testicle is called the processus vaginalis. A slightly higher incidence rate of right-sided indirect inguinal hernia is thought to reflect delay of right-sided testicular descent from the developing inferior vena cava and right external iliac vein. As the testicle descends into the scrotum, the processus vaginalis forms a serous covering around the testicle known as the tunica vaginalis. Normally, the patent processus vaginalis undergoes obliteration, closing the communication between the peritoneal cavity and the inguinal canal. A patent processus vaginalis can lead to a variety of anatomic conditions of the inguinal region (Fig. 103-6).

The incidence of patent processus vaginalis has been reported to be as high as 80% to 94% in

newborn infants undergoing autopsy,³⁴ whereas in adulthood, the incidence is 20% to 30%. Infants with unilateral inguinal hernias have been found to have a patent contralateral processus vaginalis in 60% during the first few months of life. By the age of 2 years, 20% of these hernias were obliterated, and half of the remaining 40% became clinical hernias.³⁵ At least 30% of infants requiring placement of a ventriculoperitoneal shunt for hydrocephalus have been observed to have a patent processus vaginalis in the first few months of life, with a rapid decline in patency in older children.³⁶ These studies, along with contemporary use of laparoscopic exploration of the contralateral internal ring, demonstrate that although a patent processus vaginalis is common in infancy, there is some degree of obliteration that occurs with increasing age, and a patent processus vaginalis by itself does not constitute a clinical inguinal hernia.

Figure 103-6. Anatomic variations that occur with different degrees of obliteration of the processus vaginalis. **A:** Normal; obliterated processus vaginalis. **B:** Proximal hernia sac; distal obliterated processus. **C:** Hernia sac extending into scrotum; no obliteration. **D:** Proximal and distal obliteration with hydrocele of the cord. **E:** Hydrocele of the scrotum, obliterated processus. **F:** Patent processus with communicating hydrocele.

Clinical Issues

Inguinal hernias occur in 1% to 3% of all children and in 3% to 5% of premature infants. There is no known inheritance pattern, but there is an increased incidence of inguinal hernia in children with connective tissue disorders such as Ehlers–Danlos syndrome and Marfan syndrome. There is a 6:1 predominance of males to females. At least 30% of children are younger than 6 months at the time of operative repair. Inguinal hernia more commonly presents as right-sided (56.2%) compared with left-sided (27.5%) or bilateral (16.2%).³⁷

Most infants and children have a history of an intermittent inguinal mass or bulge that may descend into the scrotum or labia. The hernia may become more pronounced during times of increased intra-abdominal pressure, such as crying or having a bowel movement. Most inguinal hernias in children reduce spontaneously or are reducible with gentle, manual pressure along the inguinal canal. Female infants may have an ovary and fallopian tube in the hernia sac, identified clinically as a firm, slightly mobile, nontender mass in the labia or the inguinal canal. Most parents or pediatricians give a

characteristic history that is sufficient to warrant inguinal exploration, even in children in whom the hernia cannot be clinically demonstrated at the time of examination. Depending on institution and surgeon preference, infants and children with a strong history consistent with inguinal hernia and an equivocal clinical examination may be offered ultrasound or diagnostic laparoscopy to effectively confirm the diagnosis before groin exploration.³⁸

Incarceration is a common consequence of untreated inguinal hernia and presents as a nonreducible mass in the inguinal canal, scrotum, or labia.³⁹ Clinical symptoms and signs are related to the duration of incarceration. If the incarceration has been present for several hours, the infant may be inconsolable and have feeding intolerance, pain, abdominal distention, vomiting, and lack of flatus or stool, signaling complete intestinal obstruction. The affected groin may become quite edematous, and a reactive scrotal hydrocele may evolve. Elevation of the infant's lower extremities with a pillow may help encourage spontaneous reduction. Attempts at manually reducing an incarcerated inguinal hernia should be performed by an experienced surgeon. If necessary, sedation to calm the infant before attempting manual reduction may be cautiously used. Ice packs should be avoided in infants and children. Following successful reduction of an incarcerated hernia, expedient elective repair of the hernia should be performed after the edema has subsided. If reduction of an incarcerated hernia requires several attempts and is difficult, overnight inpatient observation is warranted to rule out reduction of strangulated bowel; fortunately, this is an uncommon occurrence in the pediatric population. Inability to reduce an incarcerated hernia is a clear indication for urgent operative exploration and repair. Incarcerated inguinal hernia must be differentiated from an acute, noncommunicating hydrocele, or inguinal lymphadenitis. With acute hydrocele, it is usually possible to transilluminate the hydrocele and palpate normal cord structures above the scrotal mass. In addition, symptoms of bowel obstruction are absent with acute hydrocele. Acute lymphadenitis typically is associated with fever, erythema, and tenderness, and there may be a history of lower-extremity infection on the ipsilateral side. If the inguinal mass is not reducible and an incarcerated hernia cannot be excluded, urgent groin exploration is required.

Operative Considerations and Outcome

The diagnosis of inguinal hernia in an infant or a child is an indication for operative repair. The rationale for elective repair is to prevent the complications associated with incarceration. At least 71% of infants who require operative reduction of incarcerated inguinal hernia are younger than 11 months.⁴⁰ Therefore, an approach emphasizing timely elective repair of inguinal hernia is warranted, particularly during infancy. Delay of elective repair may be necessary in premature, extremely low-birth-weight (<1,500 g) infants and in children with other conditions such as congenital heart disease, pulmonary disease, infection, or metabolic disease.

Elective inguinal hernia repair in the pediatric age group is usually performed as an outpatient surgical procedure using general anesthesia, although spinal anesthesia is an effective alternative in selected high-risk infants.⁴¹ A regional caudal block or local inguinal nerve block using local anesthetic is useful to diminish perioperative pain and increase patient comfort. These techniques, along with the use of rapid-acting general anesthetics, allow the vast majority of children to be discharged home within hours of operation. Overnight observation and monitoring are required for high-risk infants and children with disorders that increase anesthetic risk for postoperative apnea.

Repair of pediatric inguinal hernia relies on high ligation of the hernia sac at the internal inguinal ring. Sensory nerves deep to the external oblique aponeurosis should be identified and preserved. Careful identification and dissection of the hernia sac from the vas deferens and the testicular blood supply must be performed. The vas deferens must be carefully dissected free from the sac, and direct handling or pinching of the vas with forceps is avoided. The absence of a vas deferens or a blind-ending vas may be observed in children with cystic fibrosis (CF). In female infants, opening the hernia sac to visualize the ovary and fallopian tube may help avoid inadvertent injury to these structures during suture ligation of the sac. The distal component of the hernia sac is opened widely, and any fluid in the sac is evacuated. If the internal inguinal ring is attenuated or enlarged, it can be repaired with a few sutures. Experience with laparoscopic inguinal hernia repair using purse-string suture closure of the patent internal ring without direct inguinal exploration has been described.⁴² The testicle is returned to its scrotal position by gentle traction on the gubernaculum, and the spermatic cord is carefully aligned along the inguinal canal. Postoperative pain is managed with oral acetaminophen for 24 to 48 hours; older children may require postoperative narcotics. In addition, abnormalities of the vas deferens may be associated with genitourinary anomalies. A renal ultrasound should be performed to rule out kidney

malformations.

Operative exploration of the asymptomatic contralateral groin remains controversial but is often performed in infants younger than 2 years because of the reported 60% to 70% incidence of a patent processus vaginalis on the opposite side.⁴³ In a survey of the surgical section of the American Academy of Pediatrics, 65% of the respondents perform contralateral exploration in male patients younger than 2 years, and 84% perform exploration for female infants up to 4 years of age.⁴⁴ Direct visualization of the contralateral groin can be performed using a laparoscope inserted either through the umbilicus or through a side-viewing laparoscope inserted through the hernia sac. Experience with diagnostic laparoscopy demonstrates that approximately one-third to one-half of children have a patent processus vaginalis on the contralateral, asymptomatic groin, with higher rates in infants younger than 1 year.^{45,46} This approach avoids unnecessary contralateral groin exploration in about half of all children who undergo surgery for unilateral inguinal hernia. However, the presence of a patent processus alone does not necessarily translate into a clinically significant hernia, and via systematic review, the reported risk of developing a metachronous contralateral inguinal hernia following open unilateral hernia repair in children is 7.2%.⁴⁷

The major risk of inguinal hernia repair in infants and children is related to general anesthesia. Complications in pediatric inguinal hernia repair include wound infection, injury to the vas deferens or testicular vessels, injury or displacement of the testicle, and recurrence. Fortunately, all these complications are infrequent. The overall complication rate is higher for children requiring emergent operation for incarcerated or strangulated hernia. Recurrent inguinal hernia following elective repair is unusual and may be an indication of an underlying connective tissue disorder such as Ehlers–Danlos syndrome.

Hydrocele

A *hydrocele* is a fluid collection that resides in the tunica vaginalis in the scrotum or the processus vaginalis in the inguinal canal. A hydrocele may be present at birth, or it may occur acutely as a result of an incarcerated hernia or torsion of the appendix testis. On examination, a hydrocele transilluminates with a bright handheld light. A hydrocele is described as either *communicating* or *noncommunicating* depending on whether there is direct patency between the hydrocele and the peritoneal cavity. A history of intermittent fluctuation in the size of the hydrocele is generally diagnostic for communicating hydrocele. A communicating hydrocele is synonymous with a patent processus vaginalis, and, therefore, a communicating hydrocele is treated operatively in the same fashion. In male patients, a hydrocele of the cord is a collection of fluid in the processus vaginalis separate from the tunica vaginalis. In female patients, fluid trapped in the processus vaginalis is considered a hydrocele of the canal of Nuck. In noncommunicating hydrocele, the isolated fluid collection is typically asymptomatic and tends to spontaneously resolve before age 12 months. Operative management of noncommunicating hydrocele is usually reserved for lesions that persist after this age, acute enlargement of the hydrocele, or if there is any question of communication.

GASTROINTESTINAL DISORDERS

Neonatal Intestinal Obstruction

3 A variety of congenital anatomic defects, inherited metabolic diseases, and acquired physiologic disorders may present as intestinal obstruction in a newborn. Neonatal intestinal obstruction is characterized clinically by bilious emesis and is often associated with abdominal distention. Bilious emesis in a neonate must be considered to be acute mechanical intestinal obstruction until proven otherwise. Emergent surgical evaluation is warranted for any newborn with bilious emesis. Table 103-2 provides differential diagnoses for neonatal intestinal obstruction along with salient features of the history, physical examination, and diagnostic studies.

DIAGNOSIS

Table 103-2 Neonatal Intestinal Obstruction

Diagnosis	History	Physical Examination	Diagnostic Studies
Intestinal atresia or stenosis	Bilious emesis	Abdominal distention	Plain abdominal film
	Failure to pass meconium	Abdominal distention	Contrast enema
Duodenal atresia or stenosis	Bilious or nonbilious emesis	Gastric distention	Plain abdominal film
	Feeding intolerance	Trisomy 21	Upper GI contrast study
Imperforate anus	Failure to pass meconium	Absent anus or visible fistula	Plain chest, abdominal film
	Bilious emesis (late)	Abdominal distention	Ultrasound kidneys, sacrum, rectum
		VACTERL association	Echocardiogram
Necrotizing enterocolitis	High-risk, premature infant	Abdominal distention	Plain abdominal film
	Bilious emesis	Abdominal wall erythema	
Meconium ileus	Cystic fibrosis (10%)	Hematochezia, guaiac positive stool	
	Bilious emesis	Acholic meconium	Plain abdominal film
Malrotation		Abdominal distention	Contrast enema
		No abdominal distention	Plain abdominal film
Hirschsprung disease	Delayed passage of meconium		Upper GI contrast study
	Bilious emesis	Abdominal distention	Plain abdominal film
Uncommon causes of obstruction (intussusception, Meckel diverticulum, duplication)		Trisomy 21	Contrast enema
		Abdominal mass, incarcerated hernia	Variable
Medical conditions associated with ileus	Bilious emesis	Sepsis, hypothyroidism, etc.	Plain abdominal film

GI, gastrointestinal; VACTERL, vertebral, anal, cardiac, tracheal, esophageal, renal, and limb anomalies.

The clinical presentation of neonatal intestinal obstruction depends, in part, on the site of obstruction and the age of the infant. Clinical examination of the infant typically provides the surgeon with a preliminary diagnosis and helps guide further diagnostic studies. Abdominal distention is a characteristic physical finding with distal bowel obstruction, whereas the abdomen may be flat in proximal obstruction. The presence of bile in the gastric contents or stool provides clinical evidence of the location of an obstruction relative to the ampulla of Vater. Bilious emesis in an infant or child should be considered an anatomic obstruction requiring emergent surgical evaluation. An infant with bilious emesis who has already passed meconium and has tolerated feeding is unlikely to have intestinal atresia and more likely to have intestinal malrotation with midgut volvulus. If volvulus is suspected, emergent evaluation must be performed to diagnose and prevent catastrophic bowel injury or death.

Definitive diagnosis of neonatal intestinal obstruction may often be made by physical examination and readily available radiologic studies. Incarcerated inguinal hernia is an important cause of neonatal bowel obstruction, and examination leads to a straightforward diagnosis. Some congenital conditions have clearly recognizable features and may be associated with anatomic intestinal obstruction. For example, infants with trisomy 21 have a higher probability of having duodenal atresia or Hirschsprung disease than the general population. An approach to imaging the neonate suspected of having an intestinal obstruction is to obtain a plain abdominal radiograph, followed by either a contrast enema or an upper gastrointestinal series. Plain films of the newborn abdomen can be extremely useful because swallowed gas acts as a contrast agent. For example, duodenal atresia gives rise to a dilated, gas-filled stomach and duodenum proximal to the obstruction; the remainder of the bowel remains gasless, giving rise to the “double-bubble” appearance on plain films. Other causes of proximal intestinal obstruction may lead to a microcolon on contrast enema, which is a small, unused but otherwise normal colon. If a retrograde contrast enema does not pass into the dilated segment of bowel, an upper gastrointestinal series may be useful to identify a more proximal obstruction. Upper gastrointestinal series is also the most useful diagnostic test for intestinal malrotation.

Several medical conditions of the newborn appear clinically similar to mechanical intestinal obstruction (see [Table 103-2](#)). In particular, bilious emesis from ileus secondary to neonatal sepsis is not uncommon. Congenital hypothyroidism is an infrequent and medically treatable condition that can produce delayed intestinal motility that mimics mechanical intestinal obstruction.

Intestinal Atresia or Stenosis

Embryology and Anatomy

The embryonic intestine undergoes segmental development during the third week of gestation. The

septum transversum demarcates the developing foregut from the midgut. The midgut can be considered a tubular structure that progressively undergoes several predictable, developmental stages: (a) elongation; (b) herniation from and reduction into the coelomic cavity; (c) rotation; and (d) fixation of the mesentery to the posterior body wall.

Several different types of intestinal atresia are clinically observed (Fig. 103-7). *Type I* atresia is an intraluminal web or diaphragm that can either be complete or fenestrated with intact seromuscular layers of bowel. *Type II* and *IIIa* atresia are believed to be a result of in utero mesenteric vascular accidents. Experimental interruption of the fetal mesenteric blood supply in utero leads to this type of atresia.^{48,49} *Type IIIb* atresia, also known as the *apple-peel* or *Christmas tree deformity*, has complete mesenteric discontinuity, with the distal bowel concentrically surrounding a singular mesenteric blood supply. *Type IV* atresia has multiple segmental areas of discontinuous bowel. *Type IIIb* and *IV* atresia are thought to be consequences of major and multiple fetal mesenteric vascular interruption.

At least 90% of infants with congenital intestinal obstruction of the small bowel have complete atresia, whereas the remaining children have either stenoses or fenestrated intraluminal webs. The most common location is the distal ileum, and multiple areas of atresia are discovered in 3.6% to 20% of these infants.³⁸ Infants with fenestrated intraluminal webs may have a small, often eccentric opening only millimeters in diameter. These infants may not have obstructive symptoms until the introduction of solid food at 6 to 12 months of age and present with feeding intolerance, failure to thrive, or abdominal pain.

Congenital colonic atresia is a distinctly unusual condition. In a contemporary series of 277 infants treated with intestinal atresia, only 21 children had colonic atresia.⁵⁰ Similar to small bowel atresia, colonic atresia is believed to reflect fetal mesenteric vascular injury. Given the distal nature of colonic atresia, initial feeding may be well tolerated and definitive diagnosis may be delayed for several days. The diagnostic evaluation and surgical treatment of colonic atresia is identical to the approach used for small bowel atresia. Colonic atresia may be associated with abdominal wall defects, skeletal or cardiac defects, or coexisting intestinal atresia.

Clinical Presentation

The actual incidence rate of congenital intestinal atresia is unknown. Reported estimates in the United States are 3.5 to 3.75 cases per 10,000 total births.⁵¹ Infants with jejunal or ileal atresia have a low incidence rate of significant associated anomalies. Approximately 10% of infants with gastroschisis have intestinal atresia or stenosis secondary to mechanical interruption of the mesenteric vascular supply.

Detection of maternal polyhydramnios on routine prenatal ultrasound screening can be an indication of proximal bowel obstruction caused by the interruption of normal amniotic fluid absorption in the fetal gut.⁵² Following delivery, the classic clinical presentation of intestinal atresia is bilious emesis, abdominal distention, and failure to pass meconium. The degree of abdominal distention depends on the site of obstruction, the infant's age, and the efficacy of proximal decompression. Abdominal distention may be absent with proximal intestinal atresia. Distal intestinal atresia may lead to abdominal distention with visible or palpable intestinal loops on examination. Rectal examination and evaluation of stool character remains important when intestinal obstruction is suspected.

Diagnosis

Following history and physical examination, plain radiographic abdominal films should be obtained. Plain films in jejunal or ileal atresia demonstrate marked gaseous distention of the proximal intestine with gasless distal small bowel and colon. Haustral markings are normally not apparent in the neonatal colon, and, therefore, discrimination between small bowel and colon in the newborn is difficult without intraluminal contrast. A contrast enema is generally obtained to confirm the diagnosis of jejunoileal atresia. A diminutive, unused but otherwise normal microcolon is typical of proximal intestinal obstruction. The inability to reflux contrast into the proximal, dilated small bowel segment is diagnostic for congenital intestinal obstruction. This radiographic finding, in conjunction with the clinical setting, warrants operative exploration. An upper gastrointestinal series is unnecessary and may increase the risk of further emesis and aspiration in the newborn with obstruction. Incomplete obstruction from a fenestrated intraluminal web may require more sophisticated imaging techniques such as catheter-directed enteroclysis.

Figure 103-7. Classification of intestinal atresia. Type I, muscular continuity with a complete web. Type II, mesentery intact, fibrous cord. Type IIIa, muscular and mesenteric discontinuous. Type IIIb, apple-peel deformity. Type IV, multiple atresias.⁵⁶

Treatment

Anatomic lesions causing neonatal intestinal obstruction require operative treatment. Whereas malrotation with midgut volvulus requires emergent diagnostic workup and operative intervention, obstruction resulting from intestinal atresia is generally not associated with life-threatening physiologic disturbances. Therefore, initial treatment is aimed at treating any other associated problems, confirming diagnosis, and preparing the infant for an operation. During this period, the infant should always have an orogastric or nasogastric tube in place to provide proximal decompression of the obstructed bowel.

The operative strategy in treating intestinal atresia is to restore gastrointestinal tract continuity while

preserving as much intestinal length as possible. The operation is straightforward and an end-to-end or end-to-oblique (end-to-back) anastomosis is typically performed (Fig. 103-8). Short-segmental bowel resection and excision of an intraluminal web or diaphragm are done when necessary. Visual inspection and instillation of intraluminal saline or air to exclude distal atresia or web prior to anastomosis is important to evaluate patency of the downstream bowel. The size discrepancy between the proximal and distal bowel is usually considerable, and delayed postoperative bowel motility is common. Some surgeons advocate the use of technical procedures to improve emptying of the proximal bowel by reducing overall bowel diameter. These procedures include resection, plication, and tapering enteroplasty. Complex atresia associated with apple-peel deformity or multiple segmental atresias may require multiple serial anastomoses to preserve as much bowel length as possible. The ileocecal valve is preserved whenever possible, allowing improved tolerance of enteral nutrition in infants with limited small bowel length. It is estimated that approximately 40 cm of small bowel without an ileocecal valve, compared with 15 to 20 cm with an ileocecal valve, is sufficient for long-term enteral feeding tolerance in the neonate.⁵³ Contemporary management of colonic atresia includes primary anastomosis when technically possible.

Results and Outcome

Currently, the overall survival rate for infants treated for intestinal atresia or stenosis (including duodenal atresia) exceeds 93% in most large series.^{50,54} Mortality in these infants is generally related to cardiac anomalies, birth weight less than 2 kg, and associated congenital anomalies.⁵⁵ Infants with a limited amount of intestinal length for nutritional absorption (short bowel syndrome with less than 40 cm) usually require long-term TPN and are at moderate to high risk for sepsis and liver injury. Infants with normal gastrointestinal length may still have prolonged intestinal dysfunction and dysmotility for several weeks.

Congenital Duodenal Obstruction

Causes of duodenal obstruction in the newborn include duodenal atresia or stenosis, duodenal intraluminal web, and annular pancreas. Because of the common embryologic basis, clinical presentation, and treatment, these entities are considered jointly.

Figure 103-8. A,B: The end-to-oblique anastomosis for small bowel atresia. C: An extension of the distal enterostomy along the

antimesenteric border may be used to create proximal and distal lumens of equal size for anastomosis.

Embryology and Anatomy

The duodenum is derived from both the caudal segment of the foregut and the cranial segment of the midgut. Duodenal development is intimately related to the developing pancreaticobiliary system. The fetal pancreas arises from paired dorsal and ventral foregut diverticula during week 6 of gestation. The dorsal anlage gives rise to the body and tail of the pancreas as well as the main pancreatic duct. The ventral anlage migrates 180 degrees to fuse with the dorsal gland, forming the uncinete process and the distal portion of the duct of Wirsung (Fig. 103-9). An annular pancreas is characterized by glandular persistence surrounding the duodenum at the site of the embryonic ventral anlage. It is invariably associated with intrinsic duodenal obstruction, and a patent accessory pancreatic duct is common (Fig. 103-10).⁵⁷

It is believed that congenital duodenal obstruction results from abnormalities of pancreatic development, failure of duodenal recanalization, or vascular compromise to the duodenum. Duodenal atresia may occur with or without seromuscular continuity, and an intraluminal duodenal web may occur with or without fenestration. The most frequent location for duodenal atresia is in the descending duodenum distal to the ampulla of Vater. Most series report a 5% to 10% incidence of duodenal atresia proximal to the ampulla, giving rise to nonbilious gastric contents and emesis. Another important variant is a periampullary web projecting distally into the duodenal or jejunal lumen, forming a “wind-sock” deformity (Fig. 103-11). In this instance, the ampulla must be clearly identified before excision and repair because of the proximity of the ampulla to the web.

Figure 103-9. Normal embryologic development of the duodenum, pancreas, and bile ducts. **A:** Fifth gestational week. **B:** Sixth week. **C:** Seventh week. **D:** Eighth week.

Clinical Presentation

The incidence rate of congenital duodenal obstruction is estimated to be about 1 in 6,000 to 10,000 births.⁵⁸ About 30% of these infants have trisomy 21.⁵⁹ Infants born with duodenal atresia should be examined with a high degree of suspicion for trisomy 21 and undergo routine karyotype analysis. Other associated anomalies such as congenital heart disease, genitourinary tract malformations, and musculoskeletal disorders are common in these infants, and appropriate preoperative workup is necessary.

Congenital duodenal obstruction most commonly presents in the first 24 to 48 hours of life with feeding intolerance and bilious emesis; duodenal obstruction proximal to the ampulla of Vater results in nonbilious emesis. On physical examination, infants with untreated duodenal obstruction may have a palpable epigastric mass, and gastric peristaltic waves may be visible. The collapsed and unused distal

small intestine typically does not produce diffuse abdominal distention. Partial duodenal obstruction from a fenestrated web may not produce symptoms in the newborn period, and delayed diagnosis is common.

Figure 103-10. Annular pancreas. **A:** The associated duodenal atresia is shown. **B:** The relationships of the annular pancreas to the common bile duct and main and accessory pancreatic ducts are shown in cross section.

Figure 103-11. Anatomic forms of duodenal atresia (**A–C**) and webs (**D,E**). In particular, (**E**) demonstrates the unique wind-sock deformity. This lesion is important and potentially confusing because the point of obstruction is not at the apparent point of change in luminal diameter.

Diagnosis

Prenatal diagnosis of duodenal atresia is possible given contemporary fetal ultrasound techniques.

Following birth, infants with suspected duodenal atresia should obtain plain abdominal radiographs. The classic radiographic finding of duodenal atresia is a double bubble from the air-filled stomach and duodenum (Fig. 103-12). In complete duodenal obstruction, no gas is seen distal to the duodenum; in this setting, the plain film is sufficiently diagnostic that no further imaging of the gastrointestinal tract is necessary. If there is incomplete obstruction, gas may be seen distally in the small or large intestine. Infants with suspected incomplete obstruction at the duodenal level may have either a fenestrated web or volvulus secondary to malrotation. Given the need for emergent operative intervention in malrotation with acute volvulus, an urgent upper gastrointestinal series with contrast should be strongly considered to exclude a neonatal surgical emergency. Importantly, all anatomic lesions causing neonatal duodenal obstruction require operative repair using a similar approach.

Treatment

Following expedient treatment of any associated life-threatening medical conditions and preoperative evaluation, the operative goals are to restore gastrointestinal continuity without sacrificing intestinal length or absorptive surface area. Because most lesions causing congenital duodenal obstruction are near the ampulla of Vater, great care must be exercised in treatment to avoid inadvertent injury to the ampulla or the pancreas.

Figure 103-12. Classic radiographic appearance of duodenal atresia. There is a double bubble of gas in the stomach and the proximal duodenum, with no gas in the distal intestinal tract.

Congenital duodenal atresia is treated by duodenoduodenostomy. Duodenal obstruction secondary to annular pancreas is also treated by duodenoduodenostomy. Direct division of annular pancreas is not performed because this does not address the underlying intraluminal duodenal obstruction, and there is significant risk of injury to the accessory pancreatic duct (see Fig. 103-10).

Duodenoduodenostomy is performed by making a transverse incision in the dilated, proximal duodenum and a longitudinal incision in the unused, downstream duodenum. The lumens are sutured together to form a diamond-shaped anastomosis (Fig. 103-13).⁶⁰ Downstream duodenal patency should be demonstrated by passing a catheter or infusing saline or air distally to avoid overlooking synchronous distal intestinal atresia. Successful and efficacious laparoscopic duodenal atresia repair has also been reported.⁶¹

Duodenal webs are excised through a longitudinal duodenotomy. The wind-sock duodenal web must be clearly identified because the visible transition from the distended, proximal duodenum to the small, downstream duodenum may be several centimeters distal to the base of the web. The ampulla of Vater must be unequivocally identified before duodenal web excision to avoid injury. Closure of the longitudinal duodenotomy is performed transversely to avoid narrowing of the duodenum.

There is usually great size discrepancy between the dilated, proximal pouch and the distal duodenal lumen, leading some surgeons to advocate procedures designed to reduce the diameter of the proximal duodenum in an effort to facilitate improved postoperative bowel motility. The efficacy of these procedures, which include tapering duodenoplasty and duodenal plication, has been described in anecdotal fashion without randomized comparison.

Results and Outcome

After successful operative repair of duodenal atresia or stenosis, delayed gastric emptying is common and typically manifests as enteral feeding intolerance. Patience and persistence are essential during the postoperative period. Surgical outcomes after repair of congenital duodenal obstruction are excellent,^{59–62} with perioperative survival exceeding 95%. Perioperative mortality is generally related to other congenital anomalies and, in particular, congenital heart disease in infants with trisomy 21. Other late problems may be encountered that reflect gastroduodenal motility issues such as poor gastric emptying, gastroesophageal reflux, and duodenal dilatation. These symptoms may appear several months to years following repair and, therefore, long-term surgical follow-up remains important.

Figure 103-13. Diamond-shaped duodenoduodenostomy for repair of duodenal atresia.

Anorectal Malformations (Imperforate Anus)

Embryology

By week 5 of gestation, the fetal cloaca is identifiable with the adjacent hindgut, allantois, and vestigial tailgut (Fig. 103-14). The mesoderm of the urorectal septum extends caudally to fuse with the cloacal closing plate. Fusion of the lateral cloacal ridges completes division of the cloaca into the rectum and the urogenital sinus. The caudal aspect of the urorectal septum forms the perineal body. The anal membrane normally ruptures during week 8 of gestation, completing the patency of the distal rectum to the skin. Further development of the urogenital sinus leads to the formation of the urethra and the bladder. In female infants, the uterus and the proximal vagina develop from the müllerian ducts. The diverse anatomic variation observed with anorectal malformations is thought to reflect anomalous or interrupted development of these structures during normal embryogenesis.

Figure 103-14. Normal embryologic division of the cloaca by the urorectal septum into the ventral urinary tract and the dorsal rectum. This process is normally completed by the ninth or tenth week of gestation.

Figure 103-15. The normal relations of the pelvic striated muscle complex and the rectum. **A:** Normal male anatomy. **B:** Coronal view showing individual components of the striated muscle complex. **C:** Sagittal view of normal anatomy.

Anatomy and Classification

The normal anatomy of the anus and the rectum is reviewed in previous chapters. Normally, the rectum descends to the perineum and ultimately to the anal orifice through a striated muscle complex in the pelvis resembling a funnel. The striated muscle complex is under voluntary control and is responsible for providing fecal continence (Fig. 103-15). Contiguous portions of the *levator ani*, the *external sphincter*, and the *puborectalis* muscles compose the *striated muscle complex*. These anatomically indistinct components of the muscle complex act together to provide control of defecation. The concept of the striated muscle complex and anatomic relationships leading to normal fecal continence with respect to anorectal malformations has evolved from both clinical and anatomic data as described by Peña.⁶³

Because of the variety of anorectal malformations observed, different classification systems have been proposed in an attempt to characterize the defects. A summary of the Wingspread Classification is provided in Table 103-3. This anatomically descriptive classification scheme is useful in planning the operative management of anorectal malformations.

CLASSIFICATION

Table 103-3 Anatomic Classification of Anorectal Malformations

Female	Male
High	
Anorectal agenesis with rectovaginal fistula without fistula	Anorectal agenesis with rectoprostatic urethral fistula ^a without fistula
Rectal atresia	Rectal atresia
Intermediate	
Rectovestibular fistula	Rectobulbar urethral fistula
Rectovaginal fistula	Anal agenesis without fistula
Anal agenesis without fistula	
Low	
Anovestibular fistula ^a	Anocutaneous fistula ^a
Anocutaneous fistula ^{a,b}	Anal stenosis ^{a,c}
Anal stenosis ^c	Rare malformations
Cloacal malformations ^d	
Rare malformations	

^aRelatively common lesion.
^bIncludes fistulas occurring at the posterior junction of the labia minora, often called *fourchette fistulas* or *vulvar fistulas*.
^cPreviously called *covered anus*.
^dPreviously called *rectocloacal fistulas*. Entry of the rectal fistula into the cloaca may be high or intermediate, depending on the length of the cloacal canal.

In male subjects, the two most common anorectal malformations observed are low imperforate anus with a perineal fistula (Fig. 103-16) and high anorectal agenesis with a rectoprostatic urethral fistula (Fig. 103-17). Male patients without a visible perineal fistula are assumed to have high imperforate anus with a rectourethral fistula until proven otherwise. In female subjects, the most common malformation encountered is low imperforate anus with a fistula from the rectum to either the perineal body or the vaginal vestibule (Fig. 103-18). As these malformations result from developmental arrest at various times during migration of the urogenital septum, considerable anatomic variability exists in both male and female subjects.

Figure 103-16. Male infant with low imperforate anus and perineal fistula. Note that the fistula is anterior to the striated muscle complex.

A common anatomic feature of imperforate anus is incomplete rectal descent to the perineum. Consequently, the rectum is not completely within the striated muscle complex. The caudal portion of the striated muscle complex remains a solid mass of striated muscle, whereas the cephalad portion may be normally positioned circumferentially around the rectal pouch. In low imperforate anus, the rectum nearly reaches the perineum, and the configuration of the striated muscle complex surrounding the rectum more closely approximates normal. With high imperforate anus, less striated muscle surrounds the rectal pouch. All anorectal malformations are considered to have some component of striated muscle complex hypoplasia and dysfunction, although the physiologic effects are variable. Low anorectal lesions have a more favorable prognosis for fecal continence than intermediate or high lesions.

Classic delineation between low and high anorectal malformations is made anatomically at the pubococcygeal line. The vast majority of low lesions have associated perineal or vestibular fistulas. High imperforate anus has a blind-ending rectal pouch above the pubococcygeal line and, therefore, above the striated muscle complex (or levator ani).

Associated Anomalies

Associated anomalies in infants with anorectal malformations are common and may be found in more than 70% of patients. The VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb) association is important and requires consideration in any infant with imperforate anus. *Vertebral anomalies* are common and include sacral dysplasia and agenesis. Infants with sacral anomalies commonly have high imperforate anus and sacral nerve dysfunction that can lead to poor long-term fecal continence and neurogenic bladder. A variety of spinal cord malformations can also be observed in these infants, including tethered spinal cord syndromes and some myelodysplastic syndromes. During the neonatal period, these spinal lesions may be detected by using ultrasound or magnetic resonance imaging (MRI), and surgical treatment may be necessary within the first 8 to 18 months of life. *Tracheoesophageal* fistula with or without esophageal atresia is estimated to occur in about 10% of infants with anorectal malformations. *Renal anomalies* are the most common associated abnormalities with anorectal malformations and include both upper and lower tract conditions. Genitourinary screening in the form of a renal ultrasound and voiding cystourethrogram is routinely performed. *Cardiac* anomalies are common and screening echocardiography is clinically indicated. *Limb abnormalities*, in particular, involvement of the radius, complete the associated anomalies defined by the acronym.

Clinical Presentation

The incidence rate of anorectal malformations is estimated at 1 in 2,524 to 5,000 live births,⁶⁴ with a slightly higher rate in males. Careful examination of the neonatal perineum reveals the diagnosis. If unrecognized and left untreated, high imperforate anus eventually leads to signs and symptoms of complete bowel obstruction characterized by abdominal distention, feeding intolerance, and bilious emesis. Because of the nearly uniform rectourethral or rectovesicular fistula in males with high lesions, some of these infants will pass meconium or gas through the urethra during urination. In contrast,

infants with low malformations typically pass meconium through a perineal or vestibular fistula within the first 24 hours of life. Occasionally, infants with large perineal fistulas are not diagnosed with an anorectal malformation until progressive constipation is noted weeks to months after birth.

In male infants, more than 95% of low malformations are associated with either a thin anal membrane or a fistula to the perineum or the scrotal raphe. The presence of a “bucket-handle” skin deformity at the presumptive anal dimple is also diagnostic of a low lesion. Infants with high malformations typically lack anal skin dimpling, have a flat gluteal contour, and may have little or absent contraction of the external sphincter with cutaneous stimulation. In female infants, 90% to 95% of low malformations have a perineal or vestibular fistula. In both male and female infants, a perineal fistula may not become apparent in the first 12 to 24 hours of life until meconium progresses distally through the rectum into the fistula.

Figure 103-17. Male infant with high imperforate anus, showing the pubococcygeal line, ischium, and striated muscle complex. **A:** The rectal pouch ends cephalad to the pubococcygeal line. This location of the rectourethral fistula is typical. **B:** Coronal view showing incomplete development of the rectal pouch within the striated muscle complex. The rectourethral fistula is shown.

Figure 103-18. Female infant with low imperforate anus and vestibular fistula.

Diagnosis

Because surgical treatment of a high or intermediate anorectal malformation is different from that of low lesion, a primary diagnostic goal is to determine whether an infant with imperforate anus has a high or low malformation. A secondary diagnostic goal is to determine the specific anorectal malformation as it relates to the rectourethral or rectovesicular fistula.

Clinical examination of an infant with low imperforate anus almost always reveals an external fistula to the perineum or the vestibule. The classic radiographic study of newborns with imperforate anus is the Wangenstein-Rice invertogram, with a lateral view of the pelvis obtained 12 to 24 hours after birth with the infant in a head-down position. This technique has been largely replaced by ultrasound-directed imaging.⁶⁵ Real-time ultrasound is currently well-accepted as an accurate method of determining the distal extent of the rectal pouch. Computed tomography (CT) imaging and MRI can be useful in evaluating the pelvic striated muscle complex in difficult cases and, in particular, cloacal malformations. MRI is also useful in evaluation of the distal spinal cord in these infants.

If there is a suspected perineal fistula or covered anus, diagnostic needle aspiration under anesthesia may be useful. Aspiration of meconium not only localizes the rectum or fistula but can also provide an estimation of the distance between the perineum and the rectum or the fistula. In general, low lesions are within 1 cm of the perineum. An infant not clearly found to have a low lesion by physical examination, radiographic studies, or examination under anesthesia should be considered to have a high anorectal malformation and treated accordingly.

A voiding cystourethrogram is generally the procedure of choice for defining the rectourethral or rectovesicular fistula. In some instances, cystoscopy is a useful adjunct before repair of high imperforate anus. For example, an infant with a large rectourethral fistula may require cystoscopic guidance of a urinary catheter to avoid inadvertent placement of the catheter through the fistula and into the rectum.

Treatment

Imperforate anus by itself is not a life-threatening condition, and, in many instances, observation for 12 to 24 hours may help delineate the presence or absence of a fistula. The surgical management of anorectal malformations has been well described elsewhere⁶³ and a brief summary follows below.

Low Malformations. Definitive repair of most low anorectal malformations can be performed in the newborn period with perineal procedures that do not require diverting colostomy. Simple dilatation of the fistula or unroofing of a covered anus may relieve the anatomic obstruction. For more complex anal stenoses or anterior perineal fistulas, a formal perineal anoplasty may be required. A common perineal procedure performed is cutback anoplasty, in which the anterior fistula or anal orifice is opened posteriorly by dividing the perineum to the external sphincter. More complex alternative approaches may be preferred in female infants with low vaginal or anterior perineal fistulas. These lesions generally require circumferential mobilization of the anterior fistula with transposition to the center of the external sphincter. Anterior reconstruction of the perineal body is then performed. Transposition anoplasty is designed to position the neoanus within the center of the external sphincter and separate the neoanus from the vaginal introitus.

Intermediate and High Malformations. Infants determined to have an intermediate, high, or indeterminate anorectal malformation generally require diverting divided colostomy as initial surgical management. Care must be taken to ensure that the proximal diverting colostomy provides adequate length and mobility of the distal colon in anticipation of eventual anorectoplasty. A divided colostomy is preferred over a loop colostomy by many surgeons to provide maximal fecal diversion from the downstream rectourinary fistula. Following diverting colostomy, a distal contrast study into the rectal pouch can also define the fistula and delineate the position of the rectum relative to the perineum.

Anorectoplasty is generally performed when the infant is approximately 8 to 12 months of age. Many different approaches have been described, and considerable personal and institutional variation is common. No single approach has superior results, and all have technical merits and difficulties. The common surgical objectives in the treatment of anorectal malformations include (a) relief of the rectal obstruction; (b) creation of a new anus; (c) position the rectum as normally as possible within the striated muscle complex; and (d) divide the rectourinary fistula. In addition, preservation of the surrounding structures (prostate, urethra, seminal vesicles, vaginal wall) is essential.

For repair of high and intermediate anorectal malformations, the most widely used procedure in the United States is the posterior sagittal anorectoplasty described in detail by Peña.⁶³ The infant is placed prone and a posterior sagittal incision following the gluteal crease is used. The external sphincter and the striated muscle complex are divided posteriorly along the midline to expose the rectal pouch. A muscle stimulator is used to define and map the striated muscle complex and to confirm symmetric dissection along the midline. Typically, the rectal pouch can be adequately dissected by this approach to allow enough length to reach the perineum. Infrequently, a combined abdominoperineal approach is required. The mobilized rectal pouch is opened and the rectourinary fistula identified and closed directly. The rectal pouch is placed centrally within the striated muscle complex, which is reconstructed circumferentially around the rectum. The neoanus is centered within the external sphincter and the mucosa is sutured to the perineum.

Other accepted and practiced surgical approaches to imperforate anus include a sacroperineal approach as proposed by Stephens,⁶⁶ and an approach that uses components of endorectal dissection as attributed to Rehbein.⁶⁷ Both these surgical procedures are characterized by blind pull-through of the distal rectum to the perineum without direct visualization of the striated muscle complex. Experience with laparoscopic dissection and division of the rectourinary fistula with perineal pull-through reconstruction has been reported.⁶⁸ It appears that personal preference, experience and familiarity rather than differences in outcome dictate the selection of procedure. In general, diverting colostomy in all of these procedures is maintained until the anorectoplasty has completely healed, after which the colostomy is closed electively.

Results, Complications, and Outcome

Mortality following anorectoplasty is related to the presence of associated congenital anomalies other than imperforate anus. A careful review of 284 infants undergoing repair of anorectal malformations observed an 18.7% mortality,⁶⁹ suggesting that this group is at moderate to high risk for complications and death secondary to coexisting congenital anomalies.

Complications are similar to other gastrointestinal surgical procedures and include infection, leak, recurrent fistula, or anastomotic stricture. Leak or stricture formation is observed in 5% to 10% of infants undergoing tapering rectoplasty during posterior sagittal anorectoplasty. Anorectal strictures are treated by gradual postoperative anal dilatation for weeks to months. Recurrent rectourethral fistula or urethral stricture is uncommon.

Long-term functional outcome in infants with low malformations is generally good given the relatively normal descent of the distal rectum within the striated muscle complex. Infants with higher lesions have a less predictable prognosis and are much more likely to have difficulty with fecal continence. Currently, the outcomes appear to be independent of the type of surgical reconstruction performed and more related to anatomic patient factors, including degree of rectal descent, integrity of the striated muscle complex, and sacral innervation. Few or perhaps none of these children have completely normal bowel habits after operation. About half of the infants have acceptable to good results with episodic fecal soilage that can be improved with bowel management programs enemas and cathartics.⁷⁰⁻⁷² A comprehensive bowel management program is essential in preventing fecal impaction and subsequent motility dysfunction in the rectum. The remaining children require major adjustments in lifestyle secondary to fecal incontinence, chronic constipation, or fecal smearing and odor. In some instances, socially acceptable continence can be assisted by the use of daily antegrade enemas via a

cecostomy or appendicostomy. In other situations, a permanent diverting colostomy may be desirable.

Necrotizing Enterocolitis

Pathophysiology

4 NEC is a neonatal disease characterized by an initial intestinal mucosal injury that may ultimately progress to transmural bowel necrosis. NEC is the most frequently encountered neonatal surgical emergency and a major cause of morbidity and mortality in the premature infant. Despite its frequency and extensive study, the pathogenesis remains obscure, and surgical treatment is directed largely at controlling the complications of intestinal necrosis. The development of NEC occurs in association with a variety of associated conditions, including perinatal stress, sepsis, respiratory failure, hypoxemia, hypotension, and congenital cardiac defects. In general, NEC is observed in the premature infant with multiple risk factors and potential etiologic events and conditions. Current clinical and experimental data support the concept that the pathophysiology of NEC remains enigmatic and multifactorial.

The intestinal mucosal injury observed in NEC is likely to be the end result of an ischemic insult in a susceptible host. Normally, the neonatal pulmonary and systemic vascular smooth muscle undergoes rapid structural and physiologic changes shortly after birth. The premature infant appears to be particularly vulnerable to vasoconstriction. With regard to NEC, it is hypothesized that hypoperfusion and ischemia of the premature neonatal intestinal tract may be the result of uncontrolled splanchnic vasoconstriction. This situation may be worsened in critically ill premature infants with low cardiac output states impairing oxygen delivery to the intestines.

A common characteristic of NEC is the host inflammatory response to the initiating mucosal injury. Experimental data are consistent with an important role for inflammatory mediators in the propagation of intestinal injury in NEC.⁷³ More than 90% of cases of NEC occur after the initiation of enteral feeding, and several studies document that the osmolarity or rate of initial feeding may be important. Although controversy exists, most neonatal centers now avoid rapid advancement of hyperosmolar enteral feedings and attempt to prevent excessive fluid volume in premature infants.^{74,75} A multicenter, randomized controlled clinical trial using *Bifidobacterium* and *Lactobacillus* as a probiotic given with initial feeding demonstrated significant reduction in death from NEC in very low-birth-weight premature infants.⁷⁶

The most common site of involvement of NEC is the terminal ileum and right colon. NEC may be localized, segmental, or it may involve the entire gastrointestinal tract. Histopathologic examination of intestinal tissue from infants with NEC demonstrates submucosal edema, hemorrhage, and microvascular thrombosis leading to transmural necrosis. The histopathology of NEC resembles that of experimental intestinal ischemia, with areas of reversible mucosal injury adjacent to areas of transmural necrosis. Dissection of intraluminal gas through the injured mucosa leads to gas within the bowel wall, known as *Pneumatosis intestinalis*. The finding of pneumatosis intestinalis is a classic radiographic and pathologic feature of NEC. Initially, the gas may be localized in the submucosa or lymphatic vessels, but it may dissect into the muscularis, the portal venous tract, or into the subserosa. Intestinal perforation, inflammatory phlegmon, and diffuse peritonitis are common with advanced NEC.

Clinical Presentation

Over the past three decades, advancements in technology, prenatal care, and neonatology have improved overall outcome in premature infants who were previously unable to survive. In the United States alone, low-birth-weight infants (less than 2,500 g) account for more than 250,000 births a year. At least half of all infants with NEC are extremely low-birth-weight infants weighing less than 1,500 g. In a study of 302 infants with NEC treated over two decades, the average birth weight fell from 1,645 to 1,505 g, and in similar fashion, the mean gestational age fell from 32.4 weeks to 30.4 weeks.⁷⁷ NEC is estimated to occur in 1 to 3 of 1,000 live births and 30 per 1,000 low-birth-weight births.⁷⁸ NEC may also occur in term infants, and in this group, it has a tendency to involve the colon and may present without classic signs.⁷⁹ The actual incidence of NEC remains difficult to determine because the diagnosis is subjective; classic signs on physical examination and diagnostic imaging are not always uniformly present. The classic clinical signs of NEC include abdominal distention, feeding intolerance, bilious emesis, and either occult or gross blood in the stool. Gastrointestinal mucosal bleeding is present in the vast majority of cases (80% to 90%) but is rarely significant from a hemodynamic standpoint. On physical examination, abdominal tenderness with distention is common, and individual loops of thickened or fixed bowel may be palpable. Edema, erythema, crepitus, or discoloration of the abdominal wall suggests intestinal necrosis, perforation, or intra-abdominal abscess (Fig. 103-19).

Hematochezia or guaiac-positive stool is typical. Systemic signs of inflammation and sepsis such as temperature instability, apnea, bradycardia, hypoxemia, acidosis, and thrombocytopenia are also common. The primary diagnostic goal during initial clinical evaluation is to determine whether irreversible, transmural intestinal necrosis is present. There is no single physical finding or laboratory test that makes this distinction.

Figure 103-19. Clinical presentation of diffuse staining of abdominal wall in an extremely low-birth-weight infant with perforated necrotizing enterocolitis.

Diagnosis

The diagnosis of NEC relies on clinical evaluation and judgment based on symptoms and signs in the appropriate setting. [Table 103-4](#) summarizes diagnostic criteria and a staging system for NEC most commonly used in the United States.⁸⁰ Radiographic confirmation of NEC requires only plain abdominal films. During the acute inflammatory phase, contrast studies may be hazardous and are contraindicated. The classic radiographic finding of pneumatosis intestinalis ([Fig. 103-20](#)) confirms the diagnosis in the appropriate clinical setting but is variably present. Other radiographic findings consistent with NEC include thickened bowel loops, ascites, and portal venous gas. Serial abdominal films, including a left lateral decubitus or upright film, should be obtained every 6 to 8 hours during the early course of the disease. These sequential studies help document the progression or resolution of the inflammatory process and, importantly, evaluate for the presence of intestinal perforation presenting as free intraperitoneal gas or pneumoperitoneum. The presence of pneumoperitoneum mandates operative intervention; however, up to half of infants with perforated NEC do not have discernible pneumoperitoneum on plain films.

Treatment

Nonoperative. The vast majority of infants with NEC can be managed medically. Initial management of NEC includes proximal decompression with a nasogastric or orogastric tube, bowel rest, and broad-spectrum intravenous antibiotics. Prompt correction of hypotension, hypoxemia, and inadequate ventilation must be undertaken. Intravenous fluid management, with particular attention to electrolytes and acid-base status, is essential. Central venous access is secured and TPN is initiated. Oxygen delivery and cardiac performance must be maintained, which in a premature neonate may require operative closure of a patent ductus arteriosus; this approach is preferable over the use of indomethacin in the setting of NEC.⁸¹ Serial physical examinations and blood work are useful in monitoring disease progress.

STAGING

Table 103-4 Necrotizing Enterocolitis

Stage I NEC (Suspected)
<i>Any one or more historical factors producing perinatal stress</i>
Systemic manifestations
Temperature instability
Lethargy
Apnea
Bradycardia
Gastrointestinal manifestations
Poor feeding
Increasing regurgitation residuals
Emesis
Mild abdominal distention
Occult blood in stool
Abdominal radiographs showing distention with mild ileus
Stage II NEC (Definite)
<i>Any one or more historical factors</i>
Above signs and symptoms, plus
Persistent occult or gross gastrointestinal bleeding
Marked abdominal distention
Abdominal radiographs showing significant intestinal distention with
Ileus
Small-bowel edema
Pneumatosis intestinalis
Portal venous gas
Stage III NEC (Advanced)
<i>Any one or more historical factors</i>
Above signs and symptoms, plus: Deterioration of vital signs
Evidence of septic shock
Marked gastrointestinal hemorrhage
Abdominal radiographs showing pneumoperitoneum in addition to findings listed for stage II
From Bell MJ, Kosloske AM, Benton C, et al. Neonatal necrotizing enterocolitis: prevention of perforation. <i>J Pediatr Surg</i> 1973;8:601–605, with permission.

Most infants with NEC improve with medical management. Typically, reversal of the systemic inflammatory response occurs rapidly, and the abdominal distention and ileus resolve over a period of days. Nasogastric tube decompression and intravenous antibiotics are usually continued for 7 to 14 days. Enteral feeding usually is resumed once antibiotics have been discontinued and there has been return of gastrointestinal function. The usual course of medically treated NEC is rapid clinical response and stabilization in the first 24 to 36 hours. Infants with significant intestinal necrosis typically have signs of either pneumoperitoneum or clinical deterioration during the initial 24 to 72 hours of treatment.

Figure 103-20. Plain abdominal film demonstrating *pneumatosis intestinalis* (arrows) in an infant with necrotizing enterocolitis.

Indications to abandon medical management and escalate surgical therapy include evidence of intestinal perforation or clinical deterioration with persistent or progressive systemic illness despite maximal medical therapy. Evidence of persistent or progressive systemic sepsis includes temperature instability, refractory hypotension, acidosis, hypoglycemia, neutropenia, and thrombocytopenia. Local findings such as portal venous gas, abdominal wall cellulitis, or crepitus also may signal intestinal necrosis and the need for operative intervention. A palpable, fixed abdominal mass consistent with intestinal perforation with an inflammatory phlegmon or abscess also may be a relative indication for operation. Because there is not complete agreement on what constitutes clinical deterioration, some controversy exists regarding operative indications for NEC in the absence of pneumoperitoneum. Because the interpretation of clinical deterioration criteria remains subjective, the decision to operate remains a multifactorial clinical judgment. In equivocal situations, abdominal paracentesis of ascitic fluid may be helpful in diagnosing intestinal necrosis with perforation in the absence of pneumoperitoneum if the aspirate contains bacteria or stool.⁸²

Operative

Operative indications in NEC include the presence of intestinal necrosis with or without frank intestinal perforation. Conventional operative intervention is aimed at treating the complications of NEC (i.e., intestinal necrosis). In general, resection of intestine involved with NEC does not prevent further extension of disease in other involved areas of the bowel. For isolated segmental disease, the traditional surgical treatment of NEC is resection of necrotic bowel with proximal enterostomy and distal mucous fistula placement. In infants with diffuse NEC, multiple resections with several enterostomies may be required. The primary operative goal is an expedient operation with preservation of as much intestinal length as possible, including the ileocecal valve. Because the risk of developing short-gut syndrome is substantial in infants with diffuse disease, preservation of marginal areas of involved intestine with a planned second-look operation to reevaluate intestinal viability may be useful. Accurate measurement of the remaining bowel length is important from a diagnostic and prognostic standpoint, with the length of bowel resected determined by the extent of transmural intestinal necrosis. Resection with primary anastomosis in selected infants with NEC has been reported,⁸³ with a recent study observing recurrent NEC in 22% and strictures in 17% of 18 treated infants following primary anastomosis.⁸⁴ Complete intestinal necrosis of the small intestine and the colon is uncommon and is not compatible with long-term survival without the sequelae of short-gut syndrome and the potential need for intestinal transplantation (Fig. 103-21).

Figure 103-21. Fulminant necrotizing enterocolitis involving the entire gastrointestinal tract in a premature infant. Note the presence of pneumatosis intestinalis.

Infants with NEC are typically fragile and premature, and complications in this population are not well tolerated. Survival in this situation may be more dependent upon disease severity and coexisting medical problems than the operative approach. For the high-risk, low-birth-weight infant, initial management with primary bedside peritoneal drainage rather than laparotomy and bowel resection may be useful as either a temporizing measure or, in some instances, a definitive procedure.⁸⁵ A multicenter, randomized controlled surgical trial comparing laparotomy with primary peritoneal drainage in premature infants with perforated NEC found that overall survival, dependence upon TPN, and length of stay were independent of the type of operation performed.⁸⁶

Complications, Results, and Outcome

Most infants with NEC are treated successfully without operative intervention. Morbidity and mortality for this group are related primarily to problems associated with prematurity. Given the delay of bowel function and the need for TPN, cholestatic jaundice commonly occurs but is generally reversible. Infants placed on broad-spectrum antibiotics for an extended period are at risk for developing fungal sepsis. For infants with intestinal necrosis from NEC, infectious complications including wound sepsis, central venous catheter infections, and pneumonia with respiratory failure may occur.

The overall surgical complication rate in infants with NEC is at least 20% to 40%. Virtually every infant with NEC has a significant complication, an associated medical problem, or both. Immediate technical complications in treating NEC include intestinal leak, fistula formation, stoma necrosis, bleeding, and liver injury during exploration (Table 103-5). These complications are obviously magnified in the extremely low-birth-weight infant with preexisting intestinal injury. Fluid and electrolyte losses from proximal diverting enterostomies can be significant and even life-threatening in extremely low-birth-weight infants whose circulating blood volume is less than 50 to 100 mL. A review of 68 infants treated surgically for NEC observed a 26% mortality rate and a 68% complication rate related to the stoma or its closure in the perioperative survivors.⁸⁷ Complications included intestinal stricture, incisional or parastomal hernia, stoma prolapse, intussusception, wound dehiscence or infection, small bowel obstruction, and anastomotic failure. The complications associated with diverting enterostomy in this unique population provide a compelling rationale for early enterostomy closure once the inflammation from peritonitis has resolved. A prospective, randomized trial comparing resection and enterostomy with resection and primary anastomosis in the treatment of NEC has not been reported.

COMPLICATIONS

Table 103-5 Operations for Necrotizing Enterocolitis

- Infection (wound, intra-abdominal, central venous catheter, pneumonia)
- Bleeding
- Stoma-related complications (stenosis, retraction, prolapse)
- Electrolyte or nutritional disturbances from enterostomy output
- Enterocutaneous fistula
- Anastomotic leak, stenosis, failure
- Adhesive small bowel obstruction
- TPN-associated cholestasis
- Short-bowel syndrome, malabsorption
- Sepsis, cardiopulmonary failure
- Intraventricular hemorrhage

Intestinal stricture formation following NEC, whether managed operatively or nonoperatively, is not uncommon. This consequence usually results from a normal host inflammatory response to transmural intestinal injury. The degree of fibrosis and subsequent stricture formation are clearly related to the severity and extent of disease. Less frequently, mesenteric vascular compromise secondary to an intra-abdominal adhesion may lead to stricture formation. Although stricture can develop anywhere in the gastrointestinal tract involved with NEC, a higher rate of demonstrable stricture is observed in the left colon, occurring in as many as 36% of medically treated infants.⁸⁸ Routine contrast enema 4 to 6 weeks after clinical resolution of NEC treated operatively or nonoperatively has been advocated in some institutions. Symptomatic strictures generally require segmental resection with anastomosis, although fluoroscopically guided balloon catheter dilatation has been reported.

Overall survival rates for infants with NEC have improved significantly over the past three decades and is currently about 60% to 80% for both operative and nonoperative groups.⁸⁹ The observed improvement in survival is thought to reflect improved neonatal intensive care, the use of TPN, and early, aggressive treatment of suspected NEC. Most neonatal intensive care units initiate aggressive medical treatment in any infant with suspected NEC. Whether surgical interventions such as resection with primary anastomosis or limited primary peritoneal drainage can improve morbidity and mortality in these critically ill infants remains to be fully determined. Long-term outcome for NEC survivors generally reflects associated problems of prematurity. In particular, many of these infants have persisting neurodevelopmental, ophthalmologic, and pulmonary diseases, but morbidity from the gastrointestinal system generally is limited to infants with short-gut syndrome following extensive bowel resection. These infants present complex ethical and management issues beyond the scope of this review. Most NEC survivors (75%) enjoy a good to excellent quality of life, suggesting that the treatment cost relative to the potential benefit for these infants is worthwhile.⁹⁰

Meconium Ileus

Meconium ileus is a descriptive term for small bowel obstruction in a newborn infant with CF. About 10% to 20% of infants with CF initially present with meconium ileus. A review of CF is useful to understand the pathophysiology and treatment of meconium ileus.

CF is the most common fatal hereditary disease in Europe and North America. It is an autosomal recessive disorder found with a heterozygous carrier incidence rate of 1 in 20 to 25 in white populations. The estimated incidence rate of homozygous gene expression and phenotypic manifestation of CF is about 1 in 2,000 to 2,500 in this population.⁹¹ The CF gene has been cloned and the single most common mutation characterized.^{92,93} The most common point mutation is a three-base-pair deletion found in 70% to 75% of the carrier population. This mutation leads to deletion of a phenylalanine residue in amino acid position 508 of the CF transmembrane conductance regulator (*CFTR*) gene. In addition, there are about 200 more infrequent mutations of the *CFTR* gene that lead to clinical CF. The molecular heterogeneity of *CFTR* gene mutations produces practical implications in the development and use of carrier screening tests in the general population. Currently, widespread use of molecular genetic screening tests in the general population to identify asymptomatic carriers and at-risk couples without a family history of CF is not recommended; there are significant technical, ethical, and social issues that must be prospectively addressed.⁹⁴ Screening of at-risk couples with a family history of CF is recommended, however, and in this setting, carrier discovery approaches 100% so that appropriate genetic counseling can be provided. Molecular genetic screening should also be offered to parents and infants with clinically suspected CF as well as asymptomatic infants born to at-risk couples. This

approach allows rapid identification and confirmation of virtually all infants homozygous for CF.

Pathophysiology

The clinical manifestations of CF are caused by an epithelial electrolyte transport defect that results in impermeability to the chloride (Cl^-) ion.⁹⁵ The epithelial defect occurs in apocrine sweat glands and the tracheobronchial tree as well as the pancreas, gastrointestinal tract, and liver. In sweat glands, failure of normal Cl^- ion reabsorption following beta-adrenergic stimulation leads to an obligate sodium chloride loss despite a normal adenosine triphosphate (ATP)-dependent sodium-potassium pump. This mechanism is the basis for the traditional diagnostic *sweat chloride test*.

Reduction of Cl^- permeability in the tracheobronchial tree leads to diminished secretion volume as well as increased absorption of sodium chloride. As a result, airway secretions in CF patients are low in volume and particularly viscous. Because of the tenacious nature of the airway secretions, airway clearance is impaired, which leads to chronic, recurrent infection with bronchitis, and pneumonia. As the disease advances, bronchiectasis and progressive pulmonary parenchymal destruction ensues. Recurrent pulmonary bacterial infection is common, and airway colonization by *Pseudomonas aeruginosa* is predictable. Chronic pulmonary disease accounts for more than 90% of the deaths in advanced CF, with a mean life expectancy approaching 30 years.

Pancreatic exocrine function is also affected by impaired Cl^- permeability. Pancreatic duct obstruction resulting from inspissated viscous secretion is followed by glandular autolysis, acinar atrophy, and pancreatic fibrosis. Pancreatic exocrine insufficiency is a classic early clinical feature of CF and is thought to account for some of the gastrointestinal manifestations of the disease. In particular, the deficiency of pancreatic proteinases, impaired chloride permeability, and abnormal epithelial mucous secretion leads to meconium ileus in the newborn, characterized by abnormally thick and viscid, protein-laden meconium that causes mechanical gastrointestinal obstruction. The obstruction is usually observed in the terminal ileum just proximal to the ileocecal valve (Fig. 103-22). Infants with meconium ileus have small pellets, or concretions, of pale, nonbilious meconium in the terminal ileum with a distal microcolon. Proximal to the obstruction, the meconium is variably mixed with gas and often is thick and tarry in consistency. The bowel containing the thick meconium is often grossly distended, and thickened. Microscopically, the muscularis is hypertrophied; distended mucous glands with prominent goblet cells may be present. The most proximal jejunum is typically normal.

Figure 103-22. Meconium ileus causing obstruction of the terminal ileum from abnormally thick, inspissated meconium.

In utero events such as proximal volvulus of the dilated segment of ileum, perforation from distention, or atresia occur in approximately one-third to one-half of fetuses with meconium ileus. These clinical entities are characterized together as *complicated meconium ileus*. A classic clinical presentation of complicated meconium ileus is in utero intestinal perforation with sterile meconium peritonitis and formation of a calcified pseudocyst (Fig. 103-23). Gastrointestinal conditions presenting later in life occur in 10% of children with CF and include acute appendicitis, recurrent rectal prolapse, and intussusception. These conditions reflect abnormal transit of thick, inspissated stool causing proximal distention or obstruction of the bowel lumen. Small-bowel obstruction in CF outside the neonatal period was historically called *meconium ileus equivalent*, and is now termed *distal intestinal obstruction syndrome* (DIOS). Treatment of DIOS is similar to initial nonoperative management of uncomplicated meconium

ileus in the newborn discussed later. Prevention of DIOS relies on conscientious pancreatic enzyme replacement. Finally, children with CF are at risk to cholestasis secondary to obstruction of small intrahepatic bile ducts. Chronic hepatic inflammation can occur with subsequent fibrosis and cirrhosis, causing hepatic failure and portal hypertension in approximately 5% of CF patients.

Diagnostic Evaluation

In nearly all newborns with CF, the diagnosis is clinically apparent by the presence of meconium ileus, a family history of CF in a sibling, or a positive newborn screening test. Laboratory confirmation of *CFTR* gene dysfunction is performed in several ways. The historical standard for the detection of CF has been analysis of the sodium chloride content of the sweat. The most commonly used and reliable technique uses pilocarpine iontophoresis, with positive sweat test results showing sodium and chloride concentrations exceeding 60 mEq/L.⁹⁶ This test is less useful during the first 4 to 6 weeks of age because normal neonates do not reliably conserve sodium chloride in sweat. Generally, abnormal *CFTR* gene is documented by two elevated sweat chloride tests obtained on separate days. With the emergence of genetic technology capable of providing accurate assessment of *CFTR* gene mutations, the sweat test is now largely used to provide clinical confirmation of *CFTR* gene dysfunction along with molecular diagnosis of CF.

Figure 103-23. A: Plain film radiograph of calcified pseudocyst in complicated meconium ileus. B: In utero ultrasound demonstrating calcified pseudocyst.

Clinical Presentation

With routine prenatal ultrasound practices along with selected fetal DNA screening, the prenatal diagnosis of CF or meconium ileus is feasible, potentially allowing for improved management of anticipated clinical problems following delivery.⁹⁷ Initial signs of meconium ileus include neonatal bowel obstruction with abdominal distention, bilious emesis, and failure to pass meconium. On examination, the neonate may have palpable loops of meconium-filled intestine with a texture on palpation described as “doughy.” Similar to other causes of proximal neonatal intestinal obstruction, rectal examination and evaluation of the meconium typically reveals clear white mucus or thick gray meconium. In utero intestinal perforation with pseudocyst formation in complicated meconium ileus may cause a palpable abdominal mass that is not particularly tender. On plain films or ultrasound, calcification is visible in the pseudocyst wall. In contrast, volvulus or intestinal perforation secondary to meconium ileus following birth generally results in diffuse peritonitis and sepsis. Intestinal atresia may also be seen as a consequence of complicated meconium ileus.

Diagnosis

Abdominal plain films may be diagnostic in meconium ileus, demonstrating multiple, distended loops of

bowel (Fig. 103-24A). Fluid- or meconium-filled loops of bowel mixed with gas give a characteristic “soap bubble” or “ground glass” appearance. Classic air-fluid levels seen in other causes of intestinal obstruction are not expected because of the tenacious, sticky intraluminal meconium. The presence of intraperitoneal calcifications or a calcified cyst is consistent with prenatal intestinal perforation of sterile meconium.

A contrast enema is useful in the evaluation and treatment of simple meconium ileus. This study usually demonstrates an unused but functionally normal microcolon (Fig. 103-24B). Reflux of contrast into the terminal ileum may confirm the presence of inspissated meconium pellets. In conjunction with a family history and plain films, this finding is sufficient evidence to confirm the diagnosis of neonatal meconium ileus. Upper gastrointestinal contrast studies are generally unnecessary and may complicate further therapeutic efforts.

Treatment

Nonoperative. Nonoperative management of simple meconium ileus is achieved in about 60% to 70% of newborns. Once the diagnosis of meconium ileus is confirmed, the initial treatment of choice is to perform retrograde irrigation of the terminal ileum with one of several solutions designed to dissipate the obstructing meconium. In the United States, several different enema techniques and a variety of contrast media have been described, including normal saline, hyperosmolar contrast agents, and dilute *N*-acetylcysteine. Initially, it was believed that using hyperosmolar contrast material was necessary to create an osmolar gradient. The resultant influx of fluid into the intestinal lumen was thought to solubilize the inspissated meconium. Recent data suggest that successful meconium clearance is not necessarily related to the osmolality of the contrast agent; however, a significantly higher overall success rate is reported with the use of Gastrografin (sodium and meglumine amidotrizoate) and the use of other solubilizing agents such as Tween-80 and *N*-acetylcysteine.⁹⁸ As long as clinical progress is being made, sequential enemas may be required to disimpact the inspissated meconium from the terminal ileum. In similar fashion, children and older patients presenting with DIOS are treated with retrograde enemas until the obstruction resolves. The distinct advantage of this treatment approach is the avoidance of general anesthesia and exploratory laparotomy. Reported complications with this approach include rare intestinal perforation, intestinal mucosal injury, and persistent obstruction resulting from meconium concretions.

Figure 103-24. A: Plain radiograph of neonate with meconium ileus. B: Contrast enema in an infant with meconium ileus demonstrating an unused but intrinsically normal microcolon.

Operative. The major indications for operative intervention are either failure to clear the obstruction by retrograde enema or complicated meconium ileus with cyst formation, volvulus, atresia, or perforation. For simple meconium ileus with persistent obstruction despite contrast enemas, the operative goals are meconium disimpaction from the ileum and evacuation of the remaining stool from the small intestine. These steps can be accomplished by either milking the meconium downstream into the colon or solubilizing the meconium by transmural needle instillation of irrigant. However, enterotomy or enterostomy and direct irrigation of the bowel lumen are usually required to completely

clear the inspissated meconium. Simple closure of the enterotomy is preferred, but segmental resection may be required if marginal or compromised intestine is found. End-to-end anastomosis is the appropriate reconstruction technique following segmental bowel resection. A temporary enterostomy may be required, and several historical techniques have been described. Another surgical option is the placement of a T-tube into the ileum for continued irrigation with dilute *N*-acetylcysteine. Following clearance of meconium from the intestine and the return of bowel function, the T-tube can be safely and simply removed.⁹⁹

Complicated meconium ileus occurs in about one-third of patients. The surgical management of this entity is individualized. Intestinal atresia is not uncommon in meconium ileus, and the entire length of the intestine must be inspected for patency. When possible, resection of nonviable, stenotic, or perforated intestine is performed with immediate reconstruction via primary anastomosis. Patency of the downstream bowel must be confirmed to prevent anastomotic leak resulting from distal obstruction. If the infant is critically ill or has diffuse peritonitis, a safe primary anastomosis may not be possible and a diverting enterostomy is required. Stoma closure may be performed promptly after resolution of peritonitis and inflammation.

Postoperative Care and Results. If the meconium has been successfully cleared without opening the intestine, dilute *N*-acetylcysteine may be given through the nasogastric tube or by enema. Alternatively, if a T-tube has been placed, dilute *N*-acetylcysteine or other irrigant can be used directly into the ileum. These efforts are aimed at keeping the meconium soluble and preventing recurrent ileal obstruction. Following return of bowel function, enteral feeding using breast milk or an elemental formula is started along with oral pancreatic enzyme replacement. Vigilant pulmonary therapy is routine and includes mucolytics and antibiotics when indicated. Nutritional assessment and support are essential in long-term management.

Successful nonoperative management of simple meconium ileus historically was associated with a more favorable outcome; however, the operative mortality rates of infants with meconium ileus have improved dramatically over the past several decades, and current short-term operative survival rates of 70% to 100% are reported.^{100,101} Long-term survival following meconium ileus is generally determined by the course of the underlying pulmonary disease. Contemporary management of CF has produced a mean survival age that approaches 30 years in most centers. With the exception of the development of portal hypertension in about 5% of patients, intestinal manifestations of the CF are treatable. Future medical and surgical efforts to improve the long-term outcome in these patients include direct replacement of the diseased pulmonary system by lung transplantation, manipulation of the epithelial chloride transport defect with pharmacologic agents, and gene therapy directed at *CFTR* gene transfer into respiratory epithelial cells.

Meconium Plug Syndrome

Meconium plug syndrome is characterized by functional obstruction of the colon or the rectum by a meconium plug. It affects both normal and premature infants with immature gastrointestinal motility and must be differentiated from other causes of neonatal intestinal obstruction. Unlike meconium ileus, in meconium plug syndrome the colon is of normal caliber and the meconium is not inspissated. The infant's symptoms within the first few days of life are abdominal distention and bilious emesis. Spontaneous passage of meconium is often absent. On examination, the infant is normal with a patent anus and a distended abdomen. Digital rectal examination may deliver the meconium plug. Plain films of the abdomen demonstrate dilated loops of bowel consistent with distal bowel obstruction. The diagnosis is confirmed by contrast enema, which is also therapeutic in helping the meconium plug pass. The meconium plug is followed by bile-stained meconium of normal consistency. Importantly, although the vast majority of these infants are normal, a few have Hirschsprung disease or CF. Therefore, infants presenting with meconium plug syndrome should undergo routine rectal suction biopsy and have CF screening tests performed.

Malrotation

Embryology

Normal midgut fixation requires sequential growth, elongation, and rotation of the intestine beginning as early as week 5 of gestation as illustrated in [Figure 103-25](#). Three distinct events occur during normal midgut fixation. The first stage involves herniation of the primary midgut loop into the base of the umbilical cord, where it remains until week 10 of gestation. The axis of the midgut loop is the superior

mesenteric artery (SMA), with the omphalomesenteric duct at the apex of the midgut loop. The midgut loop rotates 180° counterclockwise so that the proximal half passes posterior to the SMA. The proximal portion gives rise to the proximal duodenum, which lies to the right of midline. A portion of this segment becomes the third and fourth portions of the duodenum. The distal duodenum is normally fixed to the left of the aorta at the ligament of Treitz, having rotated 270 degrees counterclockwise from its original position. The jejunoileal segment undergoes dramatic elongation, forming about six primary intestinal loops. The distal midgut loop gives rise to the cecum and the right colon, which also undergoes growth and elongation with concomitant rotation 270 degrees counterclockwise. Therefore, the cecum is initially positioned to the left, then anterior, and finally to the right of the SMA before reaching its final location.¹⁰²

Reduction of the extracoelomic gut is the second stage of midgut development and fixation, occurring between weeks 10 and 12 of gestation. By this time, the duodenojejunal junction has passed posterior to the SMA and the midgut has rotated 180 degrees counterclockwise; however, the small intestine initially remains to the right side of midline, and the cecum and ascending colon are anterior to the SMA after return of the gut into the abdomen. Many common abnormalities of intestinal fixation occur as a result of arrested development during this 2-week period.

Figure 103-25. Normal midgut rotation is shown with appropriate positioning of the stomach, duodenum, small intestine, and cecum from the fifth gestational week (A) through completion by the 12th week (E).

Figure 103-26. Normal oblique fixation of the midgut mesentery at the ligament of Treitz and in the right lower quadrant. The blue portions of the colon are extraperitoneal.

The final stage of midgut development is fixation of the intestine to the posterior body wall, occurring after week 12 of gestation. Cecal descent occurs at this time. Normal points of fixation include the cecum in the right iliac fossa and the duodenojejunal junction at the ligament of Treitz just to the left of the aorta and anterior to the left renal vein (Fig. 103-26). Therefore, the normal intestinal mesentery is fixed with a broad base extending from the ligament of Treitz to the cecum. This broad-based mesenteric attachment prevents volvulus from occurring. In contrast, in disorders of intestinal rotation, the base of the mesentery is neither fixed nor broad, placing the entire midgut at risk for volvulus.

Anatomy

The normal sequence required for intestinal positioning and fixation can be interrupted at any developmental stage, producing a diverse spectrum of rotational abnormalities. Some neonatal surgical conditions are nearly always associated with abnormal intestinal rotation or fixation resulting from displacement of the midgut from the abdominal cavity during embryologic development. These anomalies include omphalocele, gastroschisis, and congenital diaphragmatic hernia. The term *malrotation* has been applied generically to describe disorders of intestinal rotation and fixation, although specific definitions of the more commonly encountered lesions are provided in the following sections.

Nonrotation. This common anomaly is characterized by inadequate counterclockwise rotation of the midgut around the SMA. Instead of the normal 270-degree arc, rotation is either absent or arrested before exceeding 90 degrees (Fig. 103-27). The small intestine resides on the right side of midline, the colon resides on the left, and the cecum is anterior and near the midline. The duodenojejunal junction is to the right of midline and more caudal and anterior in position. Nonrotation carries a significant clinical risk of midgut volvulus because the mesenteric vascular pedicle is narrow. Duodenal obstruction also may occur as a result of peritoneal attachments known as *Ladd bands*. These peritoneal bands fix the cecum to the posterior body wall by passing anterior and lateral to the distal duodenum.

Figure 103-27. Nonrotation. The proximal segment of the small intestine resides on the right side of the abdomen, and the distal segment (*colon*) is on the left. Neither has rotated normally.

Mixed or Incomplete Rotation. This rotational abnormality is characterized by arrest of the normal rotation at or near 180 degrees rather than the normal 270 degrees ([Fig. 103-28](#)). Instead of rotating posterior and to the left of the SMA, incomplete or arrested rotation of the prearterial segment leaves the duodenojejunal junction to the right of midline. The cecum also does not complete its counterclockwise passage anterior to the SMA; it usually resides in the upper abdomen just to the left of the SMA. Similar to nonrotation, fixation of the cecum to the posterior body wall by Ladd bands places the duodenum at risk for compression or obstruction. In addition, the SMA pedicle is narrow and places the midgut at risk for volvulus.

Figure 103-28. Incomplete rotation. The proximal segment has failed to rotate and is on the right. The distal segment has rotated to reside anterior to the duodenum so that cecal bands to the posterior abdominal wall may compress and obstruct the duodenum.

Mesocolic Hernias. Mesocolic hernias are rare but important anomalies characterized by failure of fixation of either the right or left mesocolon to the posterior body wall. Small bowel can become entrapped in the resulting potential cavities on either side of the abdomen. A right-sided mesocolic defect (paraduodenal hernia) is associated with nonrotation of the proximal midgut segment. Small bowel entrapment posterior to the right colon and cecum may occur. Similar entrapment of small bowel may occur from an incompletely fixed left mesocolon but is associated with normal colonic and cecal position. Entrapped small bowel in a left mesocolic hernia usually is contained within a hernia sac with the neck composed of the inferior mesenteric vein and peritoneal bands extending to the posterior body wall. Both left and right mesocolic hernias carry the potential risks of obstruction, incarceration, and

strangulation of bowel.

Clinical Presentation

Abnormalities of intestinal rotation are estimated to be present in about 1% of the population. Most persons with intestinal rotational anomalies are clinically asymptomatic; therefore, some children are found to have malrotation incidentally by upper gastrointestinal contrast studies conducted for other reasons. Symptomatic malrotation is usually encountered clinically in the setting of duodenal obstruction or midgut volvulus. Duodenal obstruction may occur as a result of Ladd bands fixing the abnormally positioned cecum to the posterior body wall. These peritoneal bands cause duodenal obstruction by extrinsic compression. Children with symptomatic duodenal obstruction typically present with bilious emesis and distention of the stomach and the proximal duodenum. Similar to proximal neonatal intestinal obstruction, newborn infants may present with bilious emesis without abdominal distention secondary to partial duodenal obstruction. A paucity of small bowel gas may be seen on plain abdominal films.

A potential consequence of intestinal malrotation is midgut volvulus. Midgut volvulus should be considered in any infant or child presenting with bilious emesis. The clinical outcome of midgut volvulus is time dependent, which is the fundamental reason that signs and symptoms of acute intestinal obstruction in an infant or a child must be pursued aggressively until a clear diagnosis is made. The devastating, life-threatening consequence of midgut volvulus is vascular insufficiency, gut ischemia, and, if untreated, infarction of the entire bowel supplied by the SMA. The initial symptoms may be subtle and limited to feeding intolerance, abdominal pain, and irritability, followed by bilious emesis. Guaiac-positive stool from mucosal injury is a common early finding. Late findings include progressive abdominal distention, hematemesis, and hypotension. Metabolic acidosis, coagulopathy, and shock may become prominent clinical features. If unrecognized or left untreated, transmural necrosis of the entire midgut will occur.

At least 50% to 75% of intestinal rotational abnormalities are discovered within the first week to month of life, and about 90% occur in children younger than 1 year.^{103,104} Symptomatic infants and children require emergent surgical exploration and correction. Older children and adults initially may present with acute volvulus but also may have a history of vague symptoms of episodic intestinal obstruction and chronic abdominal pain. It is essential to recognize that, regardless of age or chronicity of symptoms, midgut volvulus from malrotation occurs in a completely unpredictable manner.¹⁰⁵ Therefore, it is generally recommended that patients with incidentally discovered, asymptomatic malrotation undergo operative management to reduce the risk of volvulus.

Diagnosis

As with other forms of neonatal intestinal obstruction, the diagnostic evaluation begins with a plain abdominal radiograph. Classic findings with malrotation include gastric and proximal duodenal distention with a paucity or absence of distal small bowel gas (Fig. 103-29A). The plain film alone may not differentiate malrotation from duodenal atresia or stenosis. In most cases of suspected duodenal obstruction with concern of malrotation, an upper gastrointestinal series is a conclusive imaging study (Fig. 103-29B). Malrotation with volvulus typically produces incomplete duodenal obstruction with a corkscrew or coiled appearance in the distal duodenum. Extrinsic compression of the duodenum by Ladd bands may be visible on contrast study. Duodenal atresia and stenosis may occur anywhere within the duodenum but tends to be more proximal. Complete absence of small bowel gas is typical of duodenal atresia, whereas diminished but discernible distal gas is characteristic of duodenal stenosis or malrotation with volvulus.

Other radiographic findings in malrotation include incorrect position of the duodenojejunal junction, particularly to the right of midline. Failure to achieve normal cephalad and posterior fixation is typical in malrotation and may be best appreciated on lateral views. The small bowel resides in the right side of the abdomen, the colon, and cecum on the left (Fig. 103-29C). In a symptomatic infant or child, radiographic evidence of malrotation alone is enough to warrant emergent exploration. A contrast enema is helpful in the evaluation of neonatal intestinal obstruction, although it may not be the initial study of choice if malrotation is suspected. The classic finding on contrast enema for malrotation is cecal malposition, usually in the left abdomen or near the midline. Finally, the relative position of the SMA to the superior mesenteric vein may be assessed by ultrasound. Normally, the superior mesenteric vein is to the right of the SMA on transverse sonograms. Abnormal position of the superior mesenteric vein either ventral or to the left of the SMA is associated with malrotation.¹⁰⁶

Treatment

The management of bowel obstruction from malrotation or an internal hernia is operative. Initial assessment, resuscitation, and preoperative preparation in a symptomatic newborn should be conducted simultaneously so that confirmation of malrotation can be followed immediately by laparotomy. Urgent laparotomy is required to reduce the ischemic injury to the intestine. Shock, if present, must be treated aggressively by insuring adequate gas exchange and establishing restoration of intravascular volume prior to the induction of general anesthesia. Volvulus with complete infarction of the midgut, if not immediately lethal, is survivable only with enterectomy, followed by permanent or long-term TPN support. In older, asymptomatic children with incidentally discovered malrotation, operative repair remains controversial. Given the devastating consequences of midgut volvulus, however, elective surgical correction appears warranted in most asymptomatic individuals as well.

Operative repair of malrotation is performed by Ladd procedure.¹⁰⁷ The first objective is to relieve the midgut volvulus, if present. This is accomplished by delivery and detorsion of the affected midgut, usually in a counterclockwise direction. Recurrent volvulus is prevented by broadening the base of the mesenteric vascular pedicle by dividing the peritoneal bands that tether the cecum, small bowel mesentery, mesocolon, and duodenum around the base of the SMA (Fig. 103-30). Once completed, the mesentery and the mesocolon open widely and the mesenteric pedicle is at low risk for recurrent volvulus.

Figure 103-29. A: Plain radiograph of an infant with malrotation. There is a paucity of small bowel gas. B: Upper gastrointestinal contrast study demonstrating malrotation with midgut volvulus and duodenal obstruction. The position of the duodenojejunal junction is abnormal. C: Plain film showing a contrast-filled colon and cecum on the patient's left (*asterisks*). The entire small bowel is to the right of midline. These are typical radiographic findings of malrotation.

The second objective of Ladd procedure is to divide the abnormal peritoneal attachments between the

cecum and the abdominal wall. A modified Kocher maneuver involving meticulous and complete mobilization of the entire duodenum with division of all anterior, lateral, and posterior attachments is performed. Duodenal and distal small bowel patency should be demonstrated using intraluminal air or saline because synchronous intestinal webs and atresia have been reported. An appendectomy is performed to eliminate potential confusion from acute appendicitis developing in an abnormally positioned appendix. Performance of laparoscopic Ladd procedure has been demonstrated to be feasible and may help reduce time to enteral feeding and hospital length of stay; however, the long-term efficacy of this approach has been debated.¹⁰⁸ Fixation of the mesentery by cecal or duodenal plication to the body wall has been abandoned for lack of data supporting efficacy. Postoperative small bowel obstruction secondary to adhesions is reported in about 10% of patients.

Volvulus with intestinal necrosis is treated by preserving as much bowel length as possible. If bowel viability is unclear during initial exploration, a second-look procedure may be helpful to delineate reversible from irreversible injury. The management of nonviable bowel from volvulus is not different from other situations in which intestinal necrosis is encountered, and clinical decisions regarding resection and anastomosis are individualized. In situations in which the entire small intestine is lost and long-term survival is doubtful, treatment decisions must be made with the family.

Surgical management of right mesocolic hernia is directed at dividing the lateral peritoneal attachments of the cecum and right colon to eliminate the hernia. In addition, given the associated nonrotation of the proximal bowel, the vascular pedicle should be broadened as much as possible. Left mesocolic hernia is treated by mobilization of the inferior mesenteric vein, reduction of the small bowel from the hernia sac, and closure of the neck of the hernia sac to eliminate the potential space.

Results and Complications

Results following surgical correction of intestinal rotational abnormalities should be excellent, and life expectancy should be normal in the absence of intestinal necrosis. Recurrent volvulus and recurrent duodenal obstruction are distinctly unusual if the initial procedure is technically complete. Adhesive small bowel obstruction following Ladd procedure is reported in 1% to 10% of patients. Long-term outcome is obviously less favorable in patients with intestinal necrosis at the time of exploration.

Congenital Aganglionosis (Hirschsprung Disease)

Embryology

5 Congenital aganglionosis of the intestine (Hirschsprung disease) is characterized by the absence of intestinal ganglion cells. The pathogenesis of aganglionosis remains unknown. In normal development, neuroblasts derived from neural crest precursors become evident by week 5 of gestation. The neuroblasts begin maturation and caudal migration along with vagal nerve fibers. The initial caudal migration in an intermuscular plane is followed by intramural dispersal into both superficial and deep submucosal nerve plexuses. Ultimately, the neuroblasts give rise to the ganglion cells of the myenteric nervous system, with functional maturation continuing well into infancy. The orderly migration pathway of myenteric innervation has been documented in human embryos; normally, ganglion cells can be identified in the esophagus at week 6 of gestation, in the transverse colon at week 8 of gestation, and in the rectum by week 12 of gestation.¹⁰⁹

Anatomy

Hirschsprung disease is characterized by a lack of ganglion cells in the distal intestine. The length of aganglionosis is variable but most commonly involves the distal rectosigmoid colon in 75% to 80% of affected infants. In about 5% of cases, the transition zone between the normal, proximal bowel and the distal, aganglionic segment occurs in the small intestine.¹¹⁰ Discontinuous aganglionosis has been reported but should be considered distinctly unusual. Therefore, in virtually all cases, the aganglionic intestinal segment is continuous with the distal rectum to the anal verge and also includes the internal sphincter. Because of this distribution, the pathogenesis of congenital aganglionosis is often attributed

to failure of neuroblast migration. The characteristic lesion in the distal bowel is the aganglionosis in the intermuscular and submucosal plexuses. Large, hypertrophied, nonmyelinated nerve fibers are present within the muscularis mucosa, lamina propria, submucosa, and Auerbach intermuscular plexus. Both adrenergic and cholinergic fibers are prominent in the aganglionic segment, and acetylcholinesterase staining is useful diagnostically. Abnormalities in the peptidergic nervous system, including vasoactive intestinal peptide, substance P, and neurotensin immunoreactive fibers, are also described in the aganglionic bowel segment.¹¹¹ Deficient neuronal nitric oxide synthase mRNA and subsequent decreased local nitric oxide synthase activity in the aganglionic bowel have also been described.¹¹² These experimental data are consistent with the concept that a defect in nitric oxide-mediated smooth-muscle relaxation may account for some of the characteristic clinical features of Hirschsprung disease.

The transition zone between the normal, proximal bowel and the aganglionic distal bowel is distinguished grossly by distention of the proximal bowel with histologic evidence of muscular hypertrophy. The transition zone often becomes evident to direct inspection or on contrast enema during the first few weeks of life as functional obstruction leads to progressive proximal dilatation. On gross inspection, the transition zone may appear as a short funnel or cone-shaped colonic segment. The discrepancy in bowel lumen diameter is somewhat age dependent and may be subtle in a newborn or in a child with total colonic aganglionosis. Therefore, it may be difficult for the surgeon or the radiologist to define the exact transition zone site based on gross inspection or contrast enema. Gross examination alone is not sufficient for surgical decision making, and histologic confirmation of the level of ganglion cell transition is required. Given the continuous nature of aganglionosis, a rectal biopsy performed 1 to 1.5 cm above the dentate line demonstrating ganglion cells effectively excludes Hirschsprung disease.

Neuronal intestinal dysplasia is a clinically described entity similar to or associated with Hirschsprung disease.^{113,114} Despite the presence of ganglion cells, dysplastic changes in the myenteric nervous system affect bowel motility in similar fashion to aganglionosis. Clinical presentation and treatment are similar to those of classic Hirschsprung disease. There is considerable controversy regarding neuronal intestinal dysplasia, but it is reasonable to suggest that this represents an entity within the spectrum of abnormalities found in the intestinal myenteric nervous system.

Pathophysiology

Normal intestinal motility depends on coordinated propagation of segmental contraction waves immediately preceded by relaxation of the enteric smooth muscle. Patients with Hirschsprung disease lack a functional myenteric nervous system in the aganglionic segment; therefore, both propulsion and reflexive relaxation are disordered or absent in the distal bowel. Loss of neuronal nitric oxide synthase activity appears to play an important role. The internal sphincter is aganglionic and lacks the normal reflexive relaxation following rectal distention. In fact, patients with Hirschsprung disease may exhibit a paradoxical increase in sphincter tone in response to rectal distention. The functional result is tonic contraction of the aganglionic segment of bowel with ineffective peristalsis. Clinically, this presents as incomplete, distal intestinal obstruction in the newborn or as chronic constipation in the older child or adult.

Hirschsprung disease has been associated with mutations in at least three specific genes: the *RET* protooncogene, the endothelin B receptor (*EDNRB*) gene,¹¹⁵ and the endothelin 3 (*EDN3*) gene. In addition, several other candidate genes are under investigation. In mice, natural and in vitro induced mutations affecting the *RET*, *EDNRB*, and *EDN3* genes generate intestinal aganglionosis identical to Hirschsprung disease.^{116,117} Although widely accepted, it is still unknown whether the primary event in aganglionosis is failure of neuroblast migration to the distal bowel. Alternatively, ineffective microenvironmental support of neuroblasts that have already migrated may fail to promote normal neuroblast development and survival.¹¹⁸

Clinical Features

Incidence and Associations. The incidence rate of Hirsch-sprung disease is estimated at 1 per 5,000 live births with a marked male-to-female (4:1) preponderance. Most cases are sporadic, but long-segment, total colonic aganglionosis and female gender are strongly associated with familial inheritance. Genetic chromosomal analysis suggests that multiple loci may be involved, including chromosomes 13q22, 21q22, and 10q, among others.¹¹⁹ Familial Hirschsprung disease has been clearly associated with *RET* protooncogene mutations. From a clinical standpoint, mutations of the *RET* protooncogene are associated with disorders of neural crest development, namely, multiple endocrine neoplasia (MEN) types IIA and IIB as well as familial medullary thyroid carcinoma, and patients with

familial Hirschsprung disease associated with RET mutation are at risk for the development of medullary thyroid carcinoma.¹²⁰ Congenital cardiac defects are present in 2% to 5% of patients with Hirschsprung disease. Other rare congenital anomalies have been reported, but a consistent and important association is a 5% to 15% incidence of trisomy 21.¹⁰⁸ Infants presenting with meconium plug syndrome should undergo rectal suction biopsy to exclude aganglionosis.

Presentation. Most infants with Hirschsprung disease fail to pass meconium within the first 24 to 48 hours of life. Nonspecific signs of neonatal intestinal obstruction (feeding intolerance, abdominal distention, and bilious emesis) may develop. About half of the patients with Hirschsprung disease are diagnosed as neonates. Infrequently, older children or adults are diagnosed with aganglionosis during evaluation for chronic constipation. In this setting, symptoms may be minimal to disabling, and parents or patients often develop elaborate strategies to deal with chronic constipation. Abdominal distention is characteristic, and sometimes failure to thrive and malnutrition may occur. Digital rectal examination may demonstrate spasm, and, in the presence of enterocolitis, forceful expulsion of foul-smelling, liquid stool may occur.

Enterocolitis occurs in about 10% to 30% of infants and children with Hirschsprung disease and may be the presenting clinical manifestation. Enterocolitis associated with Hirschsprung disease has an unknown pathophysiology, but obstructive stasis and bacterial overgrowth are thought to be important factors. *Clostridium difficile* and rotavirus have been implicated as important pathogenic organisms; diagnostic and treatment plans should consider these possibilities. The early presenting symptoms and signs of enterocolitis include fever, abdominal distention, and diarrhea, which may be explosive, foul smelling, and bloody. Systemic sepsis, transmural intestinal necrosis, and perforation are all possible later findings. The clinical progression can be rapid, with death occurring in as few as 12 to 24 hours if treatment is not initiated. Infants are particularly vulnerable to this complication and enterocolitis accounts for virtually all mortality directly related to Hirschsprung disease in modern pediatric surgical practice. Infants with known Hirschsprung disease and suspected enterocolitis should be treated aggressively. Initial treatment includes resuscitation, broad-spectrum antibiotics, cessation of feeding, and rectal irrigation. If the enterocolitis does not respond promptly, emergent intestinal decompression with an enterostomy proximal to the transition zone is indicated.

Diagnosis

A high index of suspicion for Hirschsprung disease should be maintained for any newborn infant with abdominal distention failing to pass meconium in 24 to 48 hours. The signs of neonatal intestinal obstruction should lead to a stereotypical workup. In the presence of characteristic findings on history, examination, or radiographic studies, any infant suspected of having Hirschsprung disease should undergo rectal biopsy.

Figure 103-31. A: Contrast enema demonstrating a classic rectosigmoid transition zone (*arrow*) in Hirschsprung disease. B: Lateral view of rectum illustrates typical distal spasm of rectum. C: Operative photograph of rectosigmoid transition zone.

Plain Abdominal Radiographs. Plain film radiographs of the neonate with Hirschsprung disease are nonspecific and typically demonstrate distended, air-filled loops of bowel throughout the abdomen. It is often difficult to discriminate between small intestine and large intestine on plain films at this age, but the pattern is consistent with distal intestinal obstruction. Older children or adults may have a stool-filled megacolon on plain radiographs. In the presence of enterocolitis, thickened, dilated intestinal loops and pneumatosis intestinalis may be present.

Contrast Enema. When distal neonatal intestinal obstruction is suspected on plain abdominal films, a contrast enema should be performed. With an experienced pediatric radiologist, findings consistent with Hirschsprung disease can be accurately detected in most instances. The classic radiographic finding in Hirschsprung disease is a transition zone ([Fig. 103-31A](#)). A definitive transition zone may not be apparent in a neonate because proximal dilatation takes some time to develop. In addition, infants with short-segment disease or total colonic aganglionosis may not have obvious transition zones on contrast enema. In these instances, a lateral view of the rectum may show abnormal spasm ([Fig. 103-31B](#)). Contrast remaining in the rectum more than 24 hours following a study is suggestive of Hirschsprung disease.

Rectal Biopsy. The diagnostic standard for aganglionosis is the rectal biopsy. Several commercially available instruments capable of performing rectal suction biopsies are in widespread use. The rectal suction biopsy can be performed at bedside or in clinic without anesthesia in all newborns and most children up to several months of age. The desire for early diagnosis and the technical simplicity of the procedure allow liberal use of this technique. When applied liberally, the vast majority (85% to 90%) of infants undergoing this procedure have normal ganglion cells on biopsy, effectively excluding Hirschsprung disease. Using the rectal suction biopsy technique, a biopsy of the mucosa and the submucosa is obtained. This is sufficient to establish the diagnosis because ganglion cells are absent from all intramural plexuses in Hirschsprung disease. The biopsy must be taken 1 to 1.5 cm proximal to

the dentate line. Complications of infection, perforation, and bleeding with rectal suction biopsy are infrequent. Full-thickness rectal biopsy under general anesthesia is reserved for older children and in infants in whom suction biopsy is inadequate. An experienced pediatric pathologist must read the biopsies for maximal diagnostic accuracy. Evaluation for ganglion cells and the axons of the myenteric neurons is performed (Fig. 103-32), which may be accomplished using conventional hematoxylin-eosin staining or histochemical staining for acetylcholinesterase. Similar histochemical staining for nitric oxide synthase can be performed. These adjunctive techniques are used routinely in some centers and can help provide additional evidence of Hirschsprung disease rather than simply demonstrating aganglionosis in the biopsy specimen. Diagnostic accuracy for Hirschsprung disease is excellent with a correctly obtained rectal suction biopsy and an experienced pediatric pathologist.^{121,122}

Figure 103-32. **A:** Normal rectal biopsy with ganglion cells indicated by arrow (hematoxylin-eosin). **B:** Rectal biopsy specimen with aganglionosis (hematoxylin-eosin). Note the characteristic thickened nerve fiber (*arrow*). **C:** Normal rectal biopsy using acetylcholinesterase histochemical staining. **D:** Similarly stained specimen from a patient with Hirschsprung disease. Many thickened submucosal nerve fibers stain densely black.

Anorectal Manometry. The absence of sphincter relaxation in response to rectal dilatation is consistent with Hirschsprung disease. Because of the relative ease and accuracy of rectal suction biopsy, anorectal manometry is not widely used in the United States for the primary diagnosis of Hirschsprung disease in infancy; however, this is used in some centers around the world and, when applied carefully with an appropriate transduction probe, accurate manometric diagnosis is achievable in 85% to 90% of cases.

Treatment

Diverting colostomy should be considered for a newborn infant with Hirschsprung disease who has enterocolitis or multiple associated medical problems or anomalies. In the presence of enterocolitis, rectal irrigation and decompression can be an effective temporizing measure while resuscitation and broad-spectrum antibiotics are being instituted. Prompt proximal diversion will be required once the patient has stabilized. In the neonate, one approach following diagnosis is to perform proximal diversion by means of a colostomy (or enterostomy) placed in normal, ganglionated intestine. The diverting colostomy must be proximal to the histologic transition zone, and a series of biopsies examined by frozen section may be necessary to find the correct level for diversion. For classic rectosigmoid disease, a leveling colostomy is placed just proximal to the transition zone. This approach is generally done in two stages, with takedown of the stoma and definitive pull-through operation performed together weeks to months later, typically when the infant reaches 9 to 12 months of age. In older children, definitive pull-through is deferred until the colon has decompressed to relatively normal caliber.

For many infants and children without enterocolitis, a single-stage approach that eliminates the diverting colostomy has been advocated.^{123,124} Despite a number of different operative techniques in performing a single-stage pull-through, results and outcomes appear nearly equivalent. Definitive repair of Hirschsprung disease with a single operation is desirable from technical and economical standpoint and essentially eliminates the complications associated with neonatal stomas. As with most aspects of pediatric surgery, an increasing experience with laparoscopically assisted, single-stage pull-through operations has been reported.¹²⁵ The contemporary, laparoscopic single-stage approach in the management of Hirschsprung disease has gained wide acceptance in the pediatric surgical community and is considered by many surgeons as the current standard of care for most infants and children.

Definitive Operations for Hirschsprung Disease

The major goal of operative therapy in the treatment of Hirschsprung disease is to provide resection or bypass of the distal aganglionic rectum with the performance of a low rectal anastomosis with normally innervated proximal intestine. Numerous definitive procedures were designed to treat Hirschsprung disease, and a brief description of the principal procedures in use follows. In general, the selection of a procedure depends on a surgeon's individual training and preference rather than compelling differences in outcome.^{126,127}

Duhamel Procedure (Martin Modification). The key elements of the Duhamel procedure are illustrated in [Figure 103-33](#). After minimal pelvic dissection, resection of the aganglionic colon is performed. The aganglionic rectum is left in situ. Normal proximal colon is brought caudad into the retrorectal space, and a colorectal anastomosis is performed 1 cm above the dentate line. The original operation left the defunctionalized rectal pouch as shown, which proved problematic. The procedure has been modified by Martin to include a longer side-to-side colorectal anastomosis. Advantages of this procedure include its relative technical ease and limited pelvic dissection. Adoption of the stapled anastomosis has simplified this procedure significantly.

Figure 103-33. Duhamel procedure (Martin modification). **A:** Blunt retrorectal dissection. **B:** Incision in the posterior wall of the aganglionic rectum. **C:** Retrorectal pull-through after resection of the proximal aganglionic segment. **D:** End-to-side colorectal anastomosis preserving aganglionic rectum (as originally described). **E:** Stapled conversion of anastomosis into an extended side-to-side colorectal anastomosis (Martin modification). **F:** Completed procedure.

Soave Procedure. The Soave procedure is illustrated in [Figure 103-34](#). Following resection of aganglionic colon, an endorectal dissection in the submucosal plane is performed from proximal rectum to anus. The endorectal dissection is started in the extraperitoneal rectum. This dissection is typically much easier than similar dissection for ulcerative colitis given the lack of mucosal inflammation. The dissected rectal mucosal tube is everted through the anus, excised, and normal proximal bowel is pulled through the rectal muscular cuff. The original operation did not suture the pull-through segment of proximal bowel to the rectum. A formal sutured colorectal anastomosis is now universally performed. Care must be taken to ensure that the pull-through segment is not obstructed by the muscular cuff.

Figure 103-34. Soave endorectal procedure. **A:** Endorectal dissection initiated. **B:** Endorectal dissection complete. **C:** Eversion of the aganglionic segment and rectal mucosal tube. **D:** Incision of everted rectal tube. **E:** Endorectal pull-through. **F:** Colorectal anastomosis. **G:** Completed procedure.

Swenson Procedure. The Swenson procedure is the original definitive procedure for the treatment of Hirschsprung disease. It is somewhat more demanding from a technical standpoint, and, as such, it has been reported to have a slightly higher incidence of postoperative complications. However, long-term outcome in children who undergo a properly performed Swenson procedure is equivalent to other procedures. The basic strategy is outlined in [Figure 103-35](#). The aganglionic segment of colon is resected and a careful, nearly complete extramural dissection of the distal rectum is performed. Care must be taken to avoid inadvertent injury to the seminal vesicles, vas deferens, ureters, and pelvic splanchnic nerves. The dissected rectum is everted through the anus onto the perineum and excised. Normal proximal bowel is pulled through and a colorectal anastomosis is performed.

Laparoscopically Assisted Endorectal Pull-through. A multi-institutional clinical experience with a laparoscopically assisted endorectal pull-through technique for the treatment of Hirschsprung disease has been reported.¹²⁵ Potential advantages of this approach include excellent visibility of the distal rectum during dissection, early return of postoperative bowel function, and decreased length of hospital

stay. The early results report outcomes similar to the other established procedures. The procedure is reviewed in [Figure 103-36](#). Complete transanal excision of the distal aganglionic segment with primary coloanal anastomosis has also been performed for short-segment or typical rectosigmoid aganglionosis as well.

Rectal Myectomy. Resection of a longitudinal strip of the posterior rectal muscular wall has been used for definitive management of ultrashort-segment Hirschsprung disease. This procedure can be performed via transanal approach combined with submucosal dissection or by a posterior sagittal approach. Although controversial, the use of rectal myectomy as a definitive operation for Hirschsprung disease may be considered most useful in the selected older child identified with ultrashort-segment disease.¹²⁸

Figure 103-35. Swenson procedure. **A:** Extramural rectal dissection. **B,C:** Eversion of aganglionic segment and full-thickness rectum. **D:** Pull-through of normal, ganglionic bowel. **E:** Colorectal anastomosis. **F:** Completed procedure.

Figure 103-36. Laparoscopically assisted pull-through for Hirschsprung disease. **A:** Sites for operative trocar placement. **B:** Division of colon and rectal mesentery with mobilization of proximal colon. **C:** Circumferential incision in rectal mucosa 5- to 10-mm cephalad to the pectinate line. **D:** Mucosal traction sutures to facilitate further dissection from rectal muscular cuff. **E:** Transanal submucosal dissection is continued cephalad to meet the caudal extent of the transperitoneal rectal dissection. **F:** Circumferential incision of rectal muscular cuff. **G:** Rectal muscular cuff is split posteriorly to accommodate the pull-through segment (the pull-through segment is not shown here to clarify this maneuver). **H:** Rectum and sigmoid colon are pulled through the rectal muscular cuff to the anastomotic site. **I:** Colon is transected at appropriate site with confirmation of ganglion cells by frozen section. **J:** Transanal, end-to-end single layer colorectal anastomosis.

Total Colonic Aganglionosis. Total colonic aganglionosis is complex and, fortunately, relatively rare. Several different operative procedures have been described and treatment must be individualized. The endorectal pull-through with ileoanal anastomosis has been used with good success when most or all of the small bowel is normal. For extensive small bowel aganglionosis, an extended side-to-side

anastomosis of normally innervated proximal small bowel to the aganglionic colon has been successfully performed. For complete intestinal aganglionosis, extended intestinal myectomy has been described.

Complications and Outcome

Complications resulting from definitive procedures for Hirschsprung disease include anastomotic leak, stricture, pelvic or rectal muscular cuff abscess, intestinal obstruction, and wound infection. These occur with a frequency of 1% to 10% with most experienced pediatric surgeons. Mortality from Hirschsprung disease is distinctly unusual unless enterocolitis is the presenting feature or associated medical problems or anomalies are present.

A unique complication following definitive repair of Hirschsprung disease is postoperative enterocolitis. The clinical presentation and pathogenesis have been discussed, and it remains an important and significant cause of morbidity. The incidence of postoperative enterocolitis ranges from 10% to 30% in most large series. Although rare, Hirschsprung enterocolitis can occur even in the presence of a diverting colostomy. Long-term outcomes appear quite good for all the procedures used, with 80% to 90% of patients maintaining good to excellent bowel function.

OTHER CHILDHOOD GASTROINTESTINAL DISORDERS

This review is limited to relatively common surgical conditions that are either congenital or unique in children. For other surgical conditions that can affect both children and adults, the reader is referred to other chapters in this text.

Infantile Hypertrophic Pyloric Stenosis

Anatomy and Pathophysiology

The pathogenesis of infantile hypertrophic pyloric stenosis is unknown, but data suggest that local deficiency of neuronal nitric oxide synthase in the pylorus may be responsible for the clinical manifestations of the disease.^{129,130} The deficiency of neuronal nitric oxide synthase leads to a lack of nitric oxide-mediated relaxation of smooth muscle and subsequent pyloric obstruction. Luminal narrowing occurs as a result of concentric hypertrophy of the pyloric smooth muscle. Clinically, this presents as progressive gastric outlet obstruction that becomes symptomatic by 2 to 4 weeks of age. The maximal narrowing and clinical symptoms of hypertrophic pyloric stenosis occurs between 4 and 8 weeks of age. The hypertrophic pyloric muscle ultimately undergoes gradual involution over a period of weeks to months.

Clinical Presentation

The reported incidence rate of hypertrophic pyloric stenosis is approximately 0.1% to 0.4% among white infants and is slightly lower in the black population. There is a distinct familial predisposition with an approximate 7% incidence rate in children of parents with a history of pyloric stenosis. The incidence rate is about four times higher in males than in females and is higher in first-born infants.¹³¹ There is an apparent increased risk of hypertrophic pyloric stenosis in infants receiving oral erythromycin for pertussis prophylaxis.¹³² Association of pyloric stenosis in infants treated for esophageal atresia and in infants with Smith–Lemli–Opitz syndrome has been reported.¹³³

Infants with hypertrophic pyloric stenosis have a history of nonbilious, postprandial emesis that becomes progressively projectile. The infant otherwise appears well and will feed vigorously until late in the clinical course. The typical age at diagnosis is between ages 2 and 12 weeks of age. A history of identified feeding intolerance and formula change is common.

The definitive clinical finding on examination is a palpable, hypertrophied pylorus in the right upper quadrant to midepigastriac region, often described as a firm, mobile “olive” on examination. This is a pathognomonic finding, and in the correct clinical setting, no further diagnostic imaging studies are required. An experienced clinician should be able to palpate a hypertrophied pylorus in nearly all cases. A successful physical examination requires an empty stomach, a quiet infant, and patience; repeated examinations may be necessary. Inability to palpate the pyloric mass in a quiet or anesthetized infant should place the diagnosis of hypertrophic pyloric stenosis in question. Other physical findings include visible or palpable gastric peristaltic waves, which can also be seen with any cause of gastric or duodenal obstruction.

Late findings with advanced symptoms include dehydration and a hypochloremic, hypokalemic

metabolic alkalosis from gastric fluid losses. Profound metabolic alkalosis is less common in current practice but occasionally can be encountered in an extremely dehydrated infant with a long-standing history of emesis. The intravascular volume depletion and chloride-responsive alkalosis must be corrected prior to operative repair. The serum chloride should be restored to at least 90 to 95 mEq/L, and the measured CO_2 should be less than 30 mEq/L prior to induction of general anesthesia.

Diagnosis

If the examination is equivocal, either an upper gastrointestinal contrast series or a pyloric ultrasound examination can be performed. Both examinations are highly accurate and have sensitivity and specificity exceeding 95% in experienced hands. A typical contrast study demonstrating a narrowed, elongated pyloric channel is shown in [Figure 103-37](#). Contrast studies have the advantage of evaluating other causes of symptomatic emesis, including gastroesophageal reflux disease, malrotation, and antroduodenal webs. The disadvantage of this approach is the presence of contrast in a poorly emptying stomach. Ultrasound examination of the pylorus is a preferred diagnostic test in most pediatric institutions. Ultrasound criteria for hypertrophic pyloric stenosis include a pyloric muscle thickness of 4 mm or greater and a pyloric channel length of 15 mm or greater. In general, the diagnosis of hypertrophic pyloric stenosis is being made at an earlier age compared with several decades ago.

Figure 103-37. Infantile hypertrophic pyloric stenosis demonstrated by barium upper gastrointestinal series showing pyloric channel narrowing (N) and elongation with antral shouldering or cushioning (*arrows*).

Figure 103-38. Ramstedt pyloromyotomy for infantile hypertrophic pyloric stenosis. The cross-sectional view shows herniation of the submucosa into the myotomy site, indicative of an adequate myotomy.

Treatment

Hypertrophic pyloric stenosis is a progressive situation that subsequently resolves over several weeks to months. Nonoperative treatment during this period requires either long-term parenteral or enteral nutrition and is not practical from a risk or cost standpoint. The Ramstedt pyloromyotomy has achieved universal acceptance because it offers definitive, rapid cure in virtually all infants, and morbidity rates have been negligible (Fig. 103-38). The operation is performed once the infant is rehydrated and the serum electrolytes are corrected. Typically, the pylorus is delivered through a transverse right upper quadrant incision. A single longitudinal incision is made in the hypertrophied pyloric muscle. The hypertrophied circular pyloric muscle must be meticulously divided from the stomach to the junction of the proximal duodenum. An adequate pyloromyotomy is achieved when the submucosa bulges into the myotomy site and both edges of the divided pyloric muscle are freely mobile. Laparoscopic pyloromyotomy has been demonstrated to be efficacious and safe with similar operative times and outcome to the open repair; laparoscopic pyloromyotomy has become a standard approach at most children's hospitals.^{134,135}

Postoperative feeding typically is started within 6 to 8 hours after recovery from anesthesia. Most infants are tolerant of enteral feeding and can be discharged home safely within 24 hours of operation. The surgical treatment of pyloric stenosis is straightforward, and the recovery is typically uncomplicated. A population-based study reviewing 1,777 infants with pyloric stenosis demonstrated a shorter length of stay and a lower overall complication rate in infants operated on by specialty-trained pediatric surgeons compared to general surgeons.¹³⁶ Mortality following pyloromyotomy is distinctly unusual in the absence of concomitant medical problems. Complications are rare and usually represent wound infection, technical failures related to an inadequate pyloromyotomy, or inadvertent entry into the duodenum or the stomach. Rarely, infants with inadequate pyloromyotomy may require reexploration and a second myotomy on the posterior pyloric wall. Inadvertent duodenotomy or gastrotomy must be recognized and repaired.

Intussusception

Anatomy and Physiology

6 Intussusception is defined as the invagination or telescoping of a proximal segment of intestine into an adjacent distal segment and is the most common cause of intestinal obstruction in infants and children

aged 3 months to 3 years (Fig. 103-39). The invaginated proximal bowel is referred to as the *intussusceptum* and the recipient distal bowel is called the *intussusciens*. This process most commonly originates in the small intestine either at or near the ileocecal valve, with the terminal ileum passing into the cecum and colon (ileocolic intussusception). In the pediatric population, the vast majority (95%) of cases are considered idiopathic because of a lack of an identifiable anatomic lesion causing the intussusception. Older children are more likely to have a pathologic lead point causing the intussusception. In similar fashion, infants and children with repeated episodes of intussusception have a greater probability of a pathologic lead point. Table 103-6 describes several factors that have been associated with the development of intussusception.

Figure 103-39. Ileocolic intussusception with the intussusceptum and intussusciens indicated.

Many cases of idiopathic intussusception in infants are probably caused by the normally prominent intramural lymph nodes (Peyer patches) in the terminal ileum acting as functional lead points. The anatomic consequence of intussusception is obstruction of the distal bowel. As bowel edema and inflammation progress, mesenteric vascular insufficiency from compression and congestion may occur. Incarceration, strangulation, and intestinal perforation ultimately may result if this condition remains unrecognized or untreated.

Clinical Presentation

Intussusception is estimated to occur with an incidence rate of one to four cases per 1,000 children. There is a slight (3:2) male predominance; in a large retrospective series of children with intussusception, 79% were younger than 12 months, and seasonal variation in incidence was not observed.¹³⁷ An association between the development of intussusception and the administration of a previously available, tetravalent rhesus-based rotavirus vaccine (RotaShield, Wyeth Laboratories, Inc., Marietta, PA) was reported.¹³⁸ The currently available rotavirus vaccine does not appear to be associated with intussusception.¹³⁹

Table 103-6 Predisposing Factors Leading to Intussusception

Anatomic Lead Points
Meckel diverticulum
Polyp
Lymphatic hypertrophy (Peyer patch)

Hemophilia
Leukemia
Trauma
Blunt abdominal trauma
Major retroperitoneal dissections
Others
Cystic fibrosis

^aThese factors are more likely to be associated with small bowel-to-small bowel intussusception than with ileocolic intussusception.

Otherwise healthy infants who develop intussusception may have a characteristic clinical triad of abdominal pain, vomiting, and bloody stool. The typical infant develops the acute onset of severe, colicky abdominal pain. Intermittent episodes of irritability and crying may be associated with drawing the legs up to the abdomen. Between bouts of colic, the infant is often lethargic or sleepy. During periods of relative exhaustion, the abdominal examination may not be impressive; however, on careful physical examination, a palpable mass in the right abdomen may be appreciated in 80% to 90% of cases. Emesis is common and is often the presenting complaint. As intestinal obstruction progresses, intractable vomiting with abdominal distention and intravascular volume depletion may occur. Guaiac-positive stool is present in 90% to 95% of infants as a result of the ischemic mucosal injury to the intussusceptum. The passage of bloody stool mixed with mucus, classically described as *currant-jelly stool*, may be observed.

Diagnosis

Plain radiographs of the abdomen are generally nonspecific and may show a paucity of gas in the right lower quadrant with a mass effect in the ascending colon. Late findings demonstrate mechanical small-bowel obstruction with proximal distention, air–fluid levels, and a decrease or absence of gas distally. Diagnostic enema techniques using either air or contrast approach 100% accuracy with typical ileocolic intussusception (Fig. 103-40). An approach using hydrostatic or pneumatic enema allows therapeutic reduction of intussusception as well. Ultrasound examination typically reveals a mass resembling a bull’s eye or target sign, corresponding to the intussusceptum within the intussusciens. The target sign of intussusception also may be demonstrated by CT. Both these latter modalities do not allow for potential therapeutic reduction and may be more useful in diagnosing suspected cases of proximal jejunoileal or enteroenteral intussusception.

Figure 103-40. Contrast enema demonstrating classic ileocolic intussusception with the intussusceptum visible in the ascending colon (*arrows*).

Treatment

Any infant with suspected intussusception in the absence of peritonitis should undergo diagnostic hydrostatic or pneumatic enema. A high index of clinical suspicion and liberal application of this approach should be maintained. The incidence of normal contrast enema examinations in this setting may exceed 75% in most pediatric centers, and this is justified by the considerable risk inherent in a missed diagnosis. An experienced pediatric radiologist and surgical evaluation are essential. Intravenous access and resuscitation should occur before attempts are made at diagnostic or therapeutic enemas.

Successful hydrostatic or pneumatic reduction of ileocolic intussusception is achieved in 60% to 80% of infants in most pediatric centers in the United States. Some centers prefer pneumatic enema using air as a contrast agent, and this technique appears comparable to the hydrostatic approach in both diagnosis and therapeutic reduction of intussusception. The ability to reduce intussusception using these techniques is time dependent and diminishes substantially after the duration of symptoms exceeds 24 hours. In this setting, a contrast enema is still diagnostic and potentially therapeutic if carefully performed.¹⁴⁰ With most experienced pediatric radiologists, the risk of perforation or reduction of a strangulated intussusceptum is low.

The technique of retrograde reduction of intussusception is straightforward. Contrast or air is introduced into the rectum by a balloon catheter, with the height of the hydrostatic column 1 m or less. Most centers use three attempts at reduction, with each attempt no longer than 3 minutes in duration. As long as progress is being made, however, attempts can be repeated until reduction is achieved. Successful reduction of ileocolic intussusception is demonstrated by observing retrograde flow of contrast or air into the terminal ileum. Inability to demonstrate retrograde flow into the ileum suggests incomplete reduction requiring surgical exploration.

Operative Management. Infants presenting with peritonitis and small-bowel obstruction with a clinical diagnosis of intussusception should undergo immediate resuscitation and exploration without attempts at retrograde enema. Surgical exploration is also required after incomplete retrograde enema reduction of intussusception or in the relatively infrequent situation of bowel perforation during diagnostic or therapeutic enema. The operative strategy is dictated by the findings. Spontaneous reduction of the intussusception is reported to occur in up to 20% to 30% of infants following induction of general anesthesia. In this situation, exploration confirming the reduction and examining the bowel for a pathologic lead point is sufficient. With persistent intussusception and viable bowel, the bowel is manually reduced, generally pushing the intussusceptum out of the distal bowel. If manual reduction cannot be performed or the intussusceptum is strangulated, then segmental resection with primary anastomosis is performed. Attempts at reducing intussusception with clearly necrotic bowel should be

avoided. Diverting enterostomy as a result of peritoneal contamination usually is not required. Appendectomy is routinely performed in all infants undergoing operative exploration for intussusception. As with many aspects of pediatric surgery, a successful laparoscopic approach to the diagnosis and management of intussusception has been reported in approximately two-thirds of selected patients.¹⁴¹⁻¹⁴³

Complications and Outcome

Retrograde techniques are successful at reducing idiopathic ileocolic intussusception in 60% to 80% of cases. Following successful enema reduction, the infant is given intravenous fluids and usually observed for 24 hours. Tolerance of oral feeding is predictably rapid. Recovery from operative reduction or bowel resection is generally no different than from other similar gastrointestinal procedures. Most infants enjoy a complete recovery with minimal or no morbidity. Recurrent intussusception after either nonoperative or operative reduction occurs in about 5% of infants and usually can be treated with repeat enema. Mortality from intussusception is rare and is almost always the result of systemic sepsis and shock from unrecognized, strangulated intestine.

Figure 103-41. Normal embryonic relations of the yolk sac, yolk stalk, and developing gut.

Meckel Diverticulum and Related Disorders

Embryology and Anatomy

The most frequently encountered congenital anomaly of the gastrointestinal tract is Meckel diverticulum, representing one of several malformations resulting from persistence of the yolk stalk (synonymous with *vitelline duct* and *omphalomesenteric duct*) and its components. The embryonic yolk stalk connects the yolk sac and the developing midgut (Fig. 103-41). Between weeks 5 and 7 of gestation, the yolk sac involutes and the stalk fuses with the umbilical cord. Developmental failure or arrest of yolk sac involution creates a spectrum of clinical malformations as outlined in Figure 103-42, with Meckel diverticula constituting greater than 95% of these anomalies. Meckel diverticulum is a true diverticulum of variable size derived from the intestinal remnant of the yolk stalk. Typically, it is found on the antimesenteric border of the terminal ileum approximately 40 to 50 cm from the ileocecal valve in adults. The blood supply is derived from persistent vitelline vessels supplied from the SMA. About 25% of the diverticula have a fibrous or vascular attachment to the anterior abdominal wall at the umbilicus (Fig. 103-42C). Heterotopic gastric mucosa or pancreatic tissue is found in about half of the diverticula examined at autopsy. In about 75% of patients with symptomatic diverticula, gastric mucosa is present. When symptoms occur, bleeding or perforation is generally the result of peptic ulceration of the adjacent ileal mucosa and not from the diverticulum itself.

Clinical Presentation

Symptomatic yolk stalk anomalies are usually diagnosed by history and clinical examination. Umbilical drainage from a persistent fistula or sinus tract may be noted in a newborn following separation of the umbilical cord. Intestinal prolapse or passage of stool from the umbilicus signifies a patent omphalomesenteric duct. Small bowel obstruction in an otherwise healthy infant without a history of laparotomy may be a result of volvulus around an omphalomesenteric band or intussusception from a

Meckel diverticulum acting as a lead point.

Figure 103-42. Common variants of yolk stalk malformations. **A,B:** Meckel diverticulum can manifest with inflammation (diverticulitis) or hemorrhage from acid-induced ulceration. **C,D:** Meckel diverticulum in association with abnormal band attached to the abdominal wall predisposing to volvulus and intestinal obstruction. **E:** Patent omphalomesenteric duct. **F:** Omphalomesenteric sinus and cyst formation.

The incidence rate of Meckel diverticula in the general population is about 2%, with a 2:1 male-to-female predominance. The risk of developing symptoms from the diverticulum decreases with age, and the vast majority of subjects remain asymptomatic. About half of the persons who do become symptomatic are younger than 2 years. [Table 103-7](#) outlines several of the more common clinical presentations of symptomatic Meckel diverticulum.

Hemorrhage. Gastrointestinal bleeding related to Meckel diverticulum generally results from peptic ulceration of the adjacent ileal mucosa. Clinically, it manifests as painless, episodic hemorrhage that is typically bright red to maroon in color; melena is not characteristically seen. Bleeding from Meckel diverticulum is generally not hemodynamically significant or exsanguinating, but it can be persistent enough to require transfusion. The diagnostic test of choice is the ^{99m}Tc-pertechnetate radioisotope scan (Meckel scan) because of the high affinity of the isotope for gastric mucosa and the high probability of gastric mucosa within a symptomatic Meckel diverticulum. Diagnostic accuracy is reported to be as high as 90% for Meckel-related bleeding. Contrast studies and endoscopy have a limited role when the problem is hemorrhage from a Meckel diverticulum.

DIAGNOSIS

Table 103-7 Signs and Symptoms of Meckel Diverticulum

Clinical Presentation	Approximate Frequency (%)
Hemorrhage	30–35
Small bowel obstruction	30–35
Diverticulitis	20–25
Umbilical fistula	10
Other	Uncommon

Obstruction. Intestinal obstruction associated with omphalomesenteric duct anomalies usually results from either intussusception or volvulus around an abnormal attachment between the bowel and the abdominal wall. In about 5% to 10% of persons with symptomatic Meckel diverticula, intussusception is the initial symptom. In patients with Meckel diverticula whose initial symptom is small bowel obstruction, about half have intussusception, and the remainder have volvulus, internal hernias, or other mechanical causes. Intussusception secondary to a Meckel diverticula has a decreased likelihood for successful enema reduction. Small bowel obstruction from volvulus around an omphalomesenteric band

requires operative exploration and treatment.

Diverticulitis. About one-third of patients with symptomatic Meckel diverticulum have acute diverticulitis. Similar to appendicitis, intraluminal obstruction at the base of a Meckel diverticulum can lead to distal inflammation, gangrene, and subsequent perforation. Peptic ulceration also can lead to local inflammation and perforation with the development of peritonitis. The signs and symptoms of Meckel diverticulitis are virtually indistinguishable from appendicitis, and exploration is both diagnostic and therapeutic.

Umbilical Anomalies. About 10% of patients with yolk stalk or persistent omphalomesenteric duct anomalies have umbilical problems. The usual clinical presentation is persistent drainage or intestinal mucosa found at the umbilicus. The diagnosis can be confirmed by contrast sonogram of the umbilical orifice or tract. Occasionally, ultrasound examination may be useful to demonstrate omphalomesenteric cysts. Ultimately, surgical exploration may be required for both diagnosis and treatment.

Meckel Diverticulum as an Incidental Finding. The management of an incidentally discovered Meckel diverticulum during abdominal exploration for other reasons is controversial. The risk of resecting an asymptomatic diverticulum must be weighed against the reasons for the operative exploration, patient age, and the potential for future symptoms from the diverticulum. Infants younger than 2 years are at greater probability of becoming symptomatic from Meckel diverticula. Resection is clearly indicated with demonstration of heterotopic gastric mucosa in the diverticulum to prevent peptic ulceration. This finding may occasionally be determined by direct palpation because the gastric mucosa is thicker than ileal mucosa. Abnormal omphalomesenteric bands to the abdominal wall should also be excised. If clinical judgment suggests that the diverticulum is at risk for luminal obstruction, resection is warranted.

Treatment

Infants and children with symptomatic umbilical abnormalities from yolk stalk remnants are usually well, and umbilical exploration with possible laparotomy can be undertaken electively. The yolk stalk remnant is excised, and, if present, the communication with the ileum is closed primarily with minimal morbidity and mortality. Operative exploration is required for patients with symptomatic Meckel diverticula. Typically, exploration can be accomplished through a variety of incisions. The treatment of choice is resection through either antimesenteric wedge excision or segmental bowel resection with primary closure or anastomosis. Laparoscopic diagnosis and management of Meckel diverticulum has also been described.¹⁴⁴ In the absence of associated medical problems, excellent functional outcome is expected with minimal morbidity and essentially no mortality unless intestinal necrosis has occurred.

Foreign Bodies

Ingestion of foreign bodies by infants and children is common. Toddlers in the age range of 9 months to 2 years are at particular risk given newly acquired mobility and the tendency for oral exploration. The type of foreign body and the location in the gastrointestinal tract on discovery dictate overall management.

Esophagus

Typical foreign bodies found in the esophagus include coins and small toys. In normal children, these objects become impacted at predictably narrow portions of the esophagus, including the cricopharyngeus, the esophagus at the level of the left mainstem bronchus, and the gastroesophageal junction. Previous areas of esophageal repair or injury predispose to points of obstruction. In particular, infants and children with repaired esophageal atresia, gastroesophageal reflux, or caustic esophageal injury are at risk for impaction at these sites.

Esophageal foreign bodies produce clinical symptoms of drooling, feeding intolerance (particularly to solids), dysphagia, and pain. Unrecognized foreign bodies with unusual configuration or sharp points and edges may cause esophageal perforation and mediastinitis. The diagnosis is straightforward on plain radiographs if the object is metallic or radiopaque. If a radiolucent object is suspected, an upper gastrointestinal contrast study is usually required to confirm the diagnosis. Lateral plain films of the neck or chest may be useful to differentiate between small foreign bodies in the esophagus or the trachea.

Foreign bodies impacted in the esophagus cause partial esophageal obstruction and can cause

complications including aspiration, erosion, perforation, and late stricture formation. Therefore, all esophageal foreign bodies should be removed. Extraction of foreign objects can be accomplished by using balloon catheter retrieval under fluoroscopic guidance or direct visualization using endoscopy. Performed within 24 hours of ingestion, balloon catheter retrieval of esophageal foreign bodies is relatively straightforward. This technique is limited to smooth radiopaque objects such as coins to minimize the risk of esophageal perforation. The most significant risk with balloon catheter retrieval is potential aspiration from an unprotected airway, and this must be anticipated as the foreign body traverses the pharynx. Alternatively, for esophageal coin impaction of less than 24 hours' duration in children without a history of esophageal surgery or injury, esophageal bougienage with clearance of the coin into the stomach has been successful.¹⁴⁵

Retrieval of esophageal foreign bodies under direct endoscopic vision requires general anesthesia. Either flexible or rigid endoscopy systems are widely available and used with individual and institutional preferences. Esophageal perforation, the major risk, occurs in fewer than 5% of cases in most reported series. Longstanding esophageal foreign bodies may erode into the aorta and cause life-threatening hemorrhage from aortoesophageal fistula.¹⁴⁶

Distal Gastrointestinal Tract

More than 95% of foreign bodies that pass beyond the gastroesophageal junction proceed uneventfully through the gastrointestinal tract. The transit time for an asymptomatic foreign body is highly variable and can take hours to weeks. Progress of an asymptomatic radiopaque foreign body can be followed by abdominal plain films, but this is rarely useful from a clinical standpoint unless it is a battery. The stool may also be screened to confirm passage of a known foreign body.

Operative exploration or endoscopic retrieval of distal gastrointestinal foreign bodies is generally reserved for clinical symptoms related to either obstruction or intestinal injury heralded by abdominal pain, vomiting, fever, or peritonitis. In addition, persistence of an asymptomatic foreign body in the stomach for several weeks is a relative indication for upper endoscopic retrieval, particularly with foreign bodies with irregular shape, configuration, or sharpness. This is a clinical judgment that is best reserved for an experienced pediatric surgeon because remarkably complex and improbable objects may pass uneventfully through the gastrointestinal tract. For asymptomatic foreign bodies lodged distal to the stomach, a relative indication for operative removal is a fixed, persistent location in the intestine longer than 1 week in duration.

Ingested batteries, in particular alkaline disc batteries, are a potentially serious hazard to children and require a more aggressive approach. Disruption of the battery casing and spillage of the contents have been reported to cause intestinal injury and perforation, presumably because of leakage of potassium or sodium hydroxide. Esophageal impaction of a battery warrants prompt removal when recognized because the risk of acquired esophageal injury, perforation, and development of traumatic tracheoesophageal fistula is present.¹⁴⁷ In the distal bowel, cathartics may be helpful to expedite passage of the battery. Operative removal may be necessary if the battery fails to progress distally over a few days or if symptoms related to the battery occur. Notably, the vast majority of batteries pass through the gastrointestinal tract uneventfully. Ingestion of multiple magnets can cause problems with small bowel obstruction or enteroenteric fistula formation.

Gastrointestinal Hemorrhage

The subject of gastrointestinal hemorrhage and general principles of management are discussed elsewhere in this book. The following section reviews some of the important and age-dependent clinical causes and unique issues of gastrointestinal bleeding in pediatric population. These causes are age dependent and are summarized in [Tables 103-8](#) and [103-9](#).

Diagnostic workup of an infant or a child with gastrointestinal hemorrhage requires coordinated participation among pediatricians, surgeons, gastroenterologists, and radiologists. Several general principles governing the diagnostic approach to gastrointestinal bleeding in infants and children follow:

- a. A clear diagnosis can be made in most situations; given the current technology available to assist with diagnosis, an aggressive approach is warranted. Diagnostic procedures such as flexible fiberoptic endoscopy, radioisotope imaging, and angiography are widely available, safe, and applicable to any age group, including the newborn. Despite these measures, in approximately 16% of cases, the cause of guaiac-positive stools in a neonate or infant remains unknown,¹⁴⁸ and the bleeding is self-limited.

Table 103-8 Etiology and Causes of Upper Gastrointestinal Hemorrhage^a

Patient Age Group	Common Causes	Less Common Causes
Neonatal (0–30 days)	Gastritis Esophagitis Ingested maternal blood Peptic ulcer	Iatrogenic trauma Primary coagulopathy Vascular malformation (hemangioma, telangiectasia, arteriovenous malformation) Nasal or pharyngeal bleeding Miscellaneous (leiomyoma, gastric polyp, duplication)
Infant (30 days to 1 year)	Gastritis Esophagitis Peptic ulcer	Same as neonate, with addition of: Drugs (steroids, nonsteroidal antiinflammatory drugs) Foreign body, caustic ingestion Esophageal varices
Child (1–12 years)	Esophageal varices Esophagitis Peptic ulcer	Same as infant, with addition of: Acquired thrombocytopenia (chemotherapy)
Older child (12 years to adult)	Esophageal varices Esophagitis Peptic ulcer	Same as for child

ETIOLOGY

Table 103-9 Causes of Lower Gastrointestinal Hemorrhage^a

Patient Age Group	Common Causes	Less Common Causes
Neonatal (0–30 days)	Benign anorectal lesions (fissure) Upper gastrointestinal hemorrhage Milk allergy Necrotizing enterocolitis Midgut volvulus	Iatrogenic trauma Primary coagulopathy Vascular malformations Enterocolitis (Hirschsprung disease, other) Miscellaneous (duplication, lymphoma, lymphangiectasia)
Infant (30 days to 1 year)	Incarcerated inguinal hernia Benign anorectal lesions Idiopathic intussusception Meckel diverticulum Infectious diarrhea Upper gastrointestinal hemorrhage Milk allergy	Same as neonate, with addition of: Acquired thrombocytopenia Ingestion of colored foodstuff (pseudohematochezia)
Child (1–12 years)	Benign anorectal lesions Juvenile polyps Intussusception Meckel diverticulum Infectious diarrhea Upper gastrointestinal hemorrhage	Same as infant, with addition of: Juvenile polyposis coli/familial polyposis coli Hemolytic uremic syndrome Henöch–Schonlein purpura Systemic vasculitis (dermatomyositis, lupus) Acquired thrombocytopenia (as above plus idiopathic thrombocytopenic purpura)
Older child (12 years to adult)	Juvenile polyps Benign anorectal lesions Inflammatory bowel disease Upper gastrointestinal hemorrhage	Same as child, except: Henöch–Schonlein purpura and hemolytic uremic syndrome less likely Meckel diverticulum

*Order in appearance approximates clinical frequency.
Modified from Oldham KT, Lobe TE. Gastrointestinal hemorrhage in children. A pragmatic update. *Pediatr Clin North Am* 1985;32:1247–1263, with permission.

- b. The primary diagnostic investigation of choice for upper gastrointestinal bleeding is esophagogastroduodenoscopy. This procedure is optimally performed within the first 24 hours after cessation of active hemorrhage and usually requires general anesthesia. Imaging studies for active upper gastrointestinal hemorrhage are limited in their ability to aid with diagnosis.
- c. Infants and children presenting with minor lower gastrointestinal bleeding are best evaluated by a careful perineal and digital rectal examination, followed by anoscopy.
- d. Massive lower gastrointestinal hemorrhage in an infant or a child outside the newborn period is most likely the result of a bleeding Meckel diverticulum.

- e. If a definitive source for lower gastrointestinal hemorrhage is not found on colonoscopy, evaluation for an upper gastrointestinal source, including upper endoscopy and diagnostic laparoscopy, is warranted.
- f. Pain is an uncommon symptom with pediatric gastrointestinal hemorrhage and implies a more complex problem such as volvulus, ischemic bowel, or inflammatory bowel disease. Painful gastrointestinal hemorrhage in pediatric patient requires urgent evaluation and prompt diagnostic workup.
- g. In contrast to that in adults, gastrointestinal bleeding in children is rarely a symptom or sign of gastrointestinal neoplasm.

Neonates (0 to 30 Days of Age)

The most common cause of gastrointestinal hemorrhage in a neonate is gastritis. Endoscopic evaluation of newborns with symptomatic upper gastrointestinal hemorrhage demonstrates gastritis or esophagitis in 50% to 75% of cases. About 10% to 15% have swallowed maternal blood during birth, and 10% of newborns are found to have an underlying coagulopathy. Anatomic lesions requiring operative control are distinctly unusual in this age group. Significant and sometimes massive upper gastrointestinal hemorrhage may occur in a neonate without a definable anatomic lesion despite endoscopic evaluation. This finding is usually the result of gastritis, and treatment is directed at blood and volume replacement and correction of any underlying coagulopathy.

Significant conditions responsible for lower gastrointestinal bleeding in the newborn include NEC, malrotation with volvulus, enterocolitis, or bowel obstruction secondary to an incarcerated inguinal hernia. These clinical entities present with characteristic histories, findings on clinical examination, and surgical treatment guidelines previously discussed. Anorectal fissure is also common and easy to diagnose in neonates, and bleeding is typically self-limited.

Infants (30 Days to 1 Year)

Infants with upper gastrointestinal bleeding deserve comprehensive evaluation, including endoscopy, to identify potential lesions requiring operative intervention. The most common causes of lower gastrointestinal hemorrhage in this age group include infectious diarrhea, intussusception, food allergy, and bleeding Meckel diverticulum. Most of these lesions have distinct symptoms, signs, and diagnostic findings to facilitate diagnosis. Infectious diarrhea is usually accompanied by fever, feeding intolerance, possibly emesis, and abdominal pain. Fecal leukocytes may be present on stool examination, and enteric pathogens or their toxins can be identified by stool culture.

Children (1 to 12 Years)

An important surgical cause of upper gastrointestinal bleeding in this age group includes esophageal variceal bleeding from portal hypertension. Children with biliary atresia or extrahepatic portal venous obstruction account for most cases of variceal bleeding in this age group. In the acute setting, endoscopic sclerotherapy or banding is used as a temporizing measure for hemorrhage control; some investigators advocate maintenance sclerotherapy. Ultimately, for these children, orthotopic liver transplantation may offer definitive surgical treatment. The use of operative portosystemic shunts for acute variceal hemorrhage is not widely used in pediatric surgical practice in the United States.

Conditions causing lower gastrointestinal bleeding in this age group include juvenile polyps. These are benign, hamartomatous polyps and represent the single most common cause of lower gastrointestinal bleeding in children. About 20% to 30% of the polyps are palpable on digital rectal examination. A history of painless, bright red blood per rectum during a bowel movement is typical. The bleeding results from mucosal irritation, involution, and sloughing of a pedunculated polyp and is usually not associated with hemodynamically significant hemorrhage. Tissue may be passed or the pedunculated polyp may prolapse out the anus. A hypochromic, microcytic anemia may be present. Diagnostic workup generally involves a contrast enema to identify the polyp and evaluate the colon for synchronous lesions. Colonoscopy may require general anesthesia in this age group, and endoscopic snare polypectomy is the treatment of choice for appropriate-sized polyps. Infrequently, transanal excision or open resection of larger polyps is required. In the case of multiple juvenile polyps not amenable to endoscopic polypectomy, management may be expectant based on the benign natural history characterized by involution during adolescence. Histologic confirmation is necessary to differentiate these lesions from adenomatous polyps seen in familial polyposis syndromes or Gardner syndrome.

Older Children and Adolescents (Older Than 12 Years)

Causes of both upper and lower gastrointestinal hemorrhage in this age group include most etiologic conditions found in adults. Importantly, inflammatory bowel disease is significant in this age group.

Intestinal Duplication

The embryologic origin of enteric duplication formation remains controversial, but duplication likely represents abnormal development of either a diverticulum or adjacent portion of the developing gut. In some cases, duplication cysts of the upper gastrointestinal tract may be associated with thoracic spinal cord or vertebral defects; this association appears to reflect abnormal sequestration and integration of developing primitive notochord elements in addition to duplication. The resulting lesions are described as either *cystic* or *tubular* based on their gross appearance (Fig. 103-43). All types of gastrointestinal-derived epithelia are found, but the clinically relevant finding is ectopic gastric mucosa. Duplications are commonly found along the mesenteric border of the native bowel. The muscular wall is typically well developed and intimately attached to the functional bowel. In addition, the blood supply is also shared with the functional intestine, an important surgical consideration.

Cystic Duplications

Cystic duplications may be found throughout the gastrointestinal tract. They are frequently located in the esophagus and the hindgut, particularly the rectum. Direct communication between a duplication cyst and the functional gut lumen is unusual. Typically, asymptomatic duplications are discovered as incidental mass lesions during diagnostic imaging studies, particularly when the location is the thoracic cavity or the rectum. Duplications also may present as symptomatic lesions from ectopic gastric mucosa leading to ulceration and bleeding. Other potential presenting symptoms of enteric duplication include obstruction, intussusception, perforation or traumatic rupture, torsion, infection, and occasional malignant degeneration. Useful examinations to define the extent of the lesion include ultrasound, CT scanning, MRI studies, and contrast studies. The identification of enteric duplication on routine prenatal ultrasound examination has been reported.

Figure 103-43. Enteric duplication. **A:** Cystic duplication of the terminal ileum. **B:** Tubular duplication of the terminal ileum and the colon.

The treatment of all cystic duplications is operative. Even in asymptomatic infants and children, uncertainty regarding the nature of the mass and the potential for subsequent problems dictates surgical exploration. Esophageal and rectal duplication cysts are generally amenable to simple excision. In contrast, duplication cysts of the small intestine usually require segmental resection and primary anastomosis, given the intimate attachment and shared blood supply with the native bowel. For large cystic duplications involving longer segments of native bowel, individualized treatment strategies are required. One option is cyst marsupialization with resection of the duplication cyst wall with preservation of the common blood supply and wall between the cyst and the native bowel. This technique is combined with submucosal dissection and stripping of the remaining epithelium from the cyst wall. Another approach is internal drainage of the cyst into the adjacent native intestine, for example, creation of a cystoduodenostomy for duodenal duplication not amenable to local resection and anastomosis; this would be distinctly unusual.

Tubular Duplications

Tubular duplications may be found anywhere along the length of the gastrointestinal tract. They are less frequent than cystic duplications and have a tendency to involve the ileum and the colon. It is believed that tubular duplication generally reflects abnormal, disordered recanalization of the gastrointestinal tract. Similar to cystic duplications, tubular lesions share a common wall and blood supply with the native bowel. Communication between the tubular duplication and native bowel lumen is common. Tubular duplications may be extensive and can involve the entire length of terminal ileum and colon.

Malformations of the entire colon and rectum are associated with genitourinary anomalies, particularly duplications of the external genitalia or bladder.

Tubular duplications manifest clinically in similar fashion to cystic lesions. Symptomatic lesions most commonly present with gastrointestinal bleeding or obstruction. Treatment is operative, and an individualized strategy is required that is based on the location and nature of the duplication. Resection with primary anastomosis may require removal of an unacceptable length of normal bowel. Marsupialization with submucosal stripping of the duplication epithelium may be particularly helpful if ectopic gastric mucosa is suspected or found. Obstruction from a long, blind-ending parallel duplication that communicates with the functional gut lumen can be treated effectively with a reentry procedure such as a distal enteroenterostomy. This approach avoids a potentially complex resection of a significant length of bowel.

The outcomes of surgical management of enteric duplications are generally excellent in the absence of other associated anomalies or medical problems. Mortality attributable to the duplication itself is unusual. Postoperative morbidity is generally dependent on the nature and location of the duplication.

Mesenteric and Omental Cysts

Mesenteric and omental cysts are rare lesions thought to result from the sequestration of lymphatic tissue during development. Mesenteric cysts are twice as common as omental cysts. Both are characterized by thin, often incomplete walls lined with endothelial cells absent of surrounding smooth muscle. They may be filled with either serous lymphatic fluid or chyle and may be unilocular or multilocular. These cysts may become extraordinarily large before producing symptoms.

Most infants and children with mesenteric or omental cysts are diagnosed prior to adolescence. Asymptomatic children are usually diagnosed incidentally during studies for other reasons. Symptomatic children present with abdominal pain, and, on examination, a soft, mobile abdominal mass is characteristic. Bleeding, rupture, obstruction, torsion, or cyst infection may be observed. Most of these lesions can be diagnosed by ultrasound or CT scan imaging. Ascites, duplication cysts, pancreatic pseudocysts, and large ovarian cysts may have a similar appearance on diagnostic imaging. Peripheral calcification and evidence of recent hemorrhage may be seen in mesenteric or omental cysts (Fig. 103-44).

The treatment for these lesions is simple excision. Total excision of mesenteric or omental cysts is generally preferable over partial excision with marsupialization. Limited resection with primary anastomosis may be required for a mesenteric cyst located adjacent to the intestinal wall, particularly if there is concern that the cyst actually may be an enteric duplication. Morbidity and mortality are generally limited to concurrent problems associated with the intestine. In particular, volvulus of a mesenteric cyst may cause vascular compromise and infarction of the adjacent intestine.

Figure 103-44. Computed tomographic scan of a child after abdominal trauma. Hemorrhage into large omental cyst is apparent (arrows).

Primary Peritonitis

Bacterial peritonitis without a specific, identifiable cause is referred to as *primary peritonitis*. Spontaneous bacterial peritonitis in children with ascites or nephrosis is generally included in this group. Hematogenous seeding of ascitic fluid is probably responsible for the development of

spontaneous bacterial peritonitis. The infecting bacterial organisms were classically gram-positive with a variety of staphylococcal, streptococcal, and other species accounting for most cases. In a series of infants and children with primary peritonitis, more than two-thirds of the cases were caused by gram-negative organisms such as *Escherichia coli*.¹⁴⁹ This trend may reflect the use of antibiotic prophylaxis directed against gram-positive organisms.

The other etiologic mechanism for the development of primary peritonitis is believed to involve retrograde inoculation of the peritoneal cavity via the genitourinary tract. This etiology is characteristic of prepubertal girls 5 to 10 years of age, accounting for as many as half of the cases of primary peritonitis. The initial signs and symptoms in these children are virtually identical to those in children with perforated appendicitis: fever, emesis, abdominal pain, and tenderness on examination. Leukocytosis is characteristic, and an ileus is observed on plain abdominal films. On exploration, these children have inflammatory peritonitis without an identifiable enteric cause. Gram-negative enteric organisms are commonly cultured from the peritoneal fluid.

Infants and children with peritonitis in association with an indwelling peritoneal dialysis catheter or ventriculoperitoneal shunt may be treated successfully with intravenous broad-spectrum antibiotics. The catheter or shunt should be removed or exteriorized promptly if peritonitis does not resolve within 24 to 48 hours.¹⁵⁰ In association with ascites or nephrosis, diagnostic paracentesis should be performed and the peritoneal fluid examined by Gram stain and culture. If there is any diagnostic uncertainty, laparoscopic or open operative exploration may be required to exclude intestinal perforation as a cause of peritonitis. If the appendix is normal, peritoneal cultures should be obtained and a thorough, complete abdominal exploration for other causes should be performed. Appendectomy is generally performed when the diagnosis of primary peritonitis is established by a right lower-quadrant incision. Other than perforated appendicitis, distinct causes of intestinal perforation or peritonitis in this age group include perforated Meckel diverticulum, duodenal ulcer, and acute pancreatitis. About half of the peritoneal fluid cultures are positive for a single organism. Treatment with specific antibiotics is continued until the patient is afebrile with a normal white blood cell count and normal clinical examination. Following operative exploration in primary peritonitis, the morbidity is no different than that for appendectomy, and the recovery is generally uneventful.

ETIOLOGY

Table 103-10 Common Causes of Neonatal Ascites

Maternal-fetal Rh incompatibility (rare)
Structural malformations

Cytomegalovirus
Others
α_1 -Antitrypsin deficiency
Idiopathic

Ascites

The common causes of neonatal and childhood ascites are listed in [Tables 103-10](#) and [103-11](#). The clinical presentation is that of abdominal distention with bulging flanks and demonstrable fluid on palpation and percussion. Ultrasound or CT scan imaging may be useful to confirm the clinical diagnosis. Paracentesis and routine examination of the fluid for Gram stain, cell count, cytology, protein, chemistries, and culture should be performed. Chylous ascites is characterized by a white milky appearance, high lymphocyte count, and high triglyceride content. Bile-stained fluid in the absence of

demonstrable bowel perforation is characteristic of biliary ascites. High-fluid amylase content is seen in pancreatic ascites, and a low protein count (<3 g/dL) is consistent with serous ascites. Elevated urea nitrogen or creatinine in the fluid may suggest urinary ascites, particularly in a male patient. Cytology should be performed to exclude peritoneal ascites secondary to malignancy, particularly in pubertal and adolescent females.

If the initial fluid does not provide a diagnosis in an otherwise normal-appearing child, a comprehensive diagnostic imaging evaluation is warranted. An echocardiogram should be obtained and either ultrasound or CT scan imaging performed to evaluate the genitourinary system, the hepatobiliary system, and the pancreas. A voiding cystourethrogram may also be indicated.

Treatment of neonatal or childhood ascites depends on the establishment of a specific diagnosis. In the absence of anatomic lesion or injury, spontaneous resolution of chylous ascites occurs in 50% to 75% of cases with the temporary cessation of enteral feeding and administration of parenteral nutrition. Persistence of chylous ascites for longer than 4 to 6 weeks is an indication for operative attempts to ligate the cisterna chyli. Neonatal biliary ascites may result from spontaneous bile duct perforation, in which case a diagnosis of CF must be considered. Transient bile duct obstruction typically leads to perforation at the junction of the cystic duct with the common duct. Simple external drainage is the treatment of choice, and complex hepatobiliary tract reconstruction in this setting is unnecessary and potentially hazardous. Urinary ascites in a male patient requires a workup that includes a voiding cystourethrogram to exclude posterior urethral valves. Urinary ascites resolves with the treatment of obstructive uropathy. Pancreatic ascites is typically self-limited, and treatment by drainage procedures is generally not required or limited for relief of persistent symptoms.

ETIOLOGY

Table 103-11 Common Causes of Childhood Ascites

Serous Ascites
Cirrhosis
Budd–Chiari syndrome
Nephrosis
Right-sided heart failure
Postoperative ascites (after renal transplantation, peritoneal dialysis, ventriculoperitoneal shunt)
α_1 -Antitrypsin deficiency
Other rare metabolic disorders
Chylous Ascites
Malrotation with volvulus
Small bowel obstruction
Incarcerated hernia
Lymphangioma
Trauma (includes operative trauma)
Biliary Ascites
Neonatal bile duct perforation
Cystic fibrosis
Biliary atresia
Hepatitis
Cytomegalovirus infection
Urinary Ascites (7:1 Male Predominance)
Urinary obstruction
Posterior urethral valves
Bladder perforation
Ureterocele
Neurogenic bladder
Pancreatic Ascites
Acute pancreatitis (drugs, trauma, gallstones, infection)
Pancreatic pseudocysts
Ovarian Ascites
Cysts (torsion, rupture)
Tumors
Malignant Ascites
Intra-abdominal neoplasm
Idiopathic

Massive neonatal ascites may cause hypoventilation secondary to impairment of diaphragmatic excursion, and therapeutic paracentesis may be required. Childhood ascites generally responds to adequate treatment of the underlying problem and occasionally requires medical therapy. Placement of a peritoneovenous shunt in children for intractable ascites is rare.

Rectal Prolapse

Spontaneous rectal prolapse is relatively common in toddlers and children up to 5 years of age. A peak incidence occurs at or near the time of toilet training. There is an association between straining during bowel movement and rectal prolapse; it may be more commonly observed in children with CF, myelodysplasias with sacral neuropathy, congenital anorectal malformations, Hirschsprung disease, and colorectal polyps. However, most children presenting with rectal prolapse are normal.

A history of protrusion of mucosa or full-thickness rectum with or without bleeding is usually described. Other lesions of childhood that have a similar appearance are prolapse of an intussusceptum or passage of a polyp through the anus. The rectal examination is diagnostic. If the protruding intestine is an intussusceptum, a finger can be placed adjacent to it within the rectum; this maneuver is not possible with rectal prolapse.

Nonoperative management using manual reduction is successful in most infants and children. Sedation may be required in some instances. Therapeutic interventions include stool softeners and parental instruction on manual reduction. Spontaneous resolution over a few weeks is typical. For persistent rectal prolapse in children, operative intervention is generally governed by doing the least invasive procedure possible. Unlike adults, complex operations involving bowel resection and pelvic suspension

are generally unnecessary in children with rectal prolapse. The most useful and commonly used procedure is rectal submucosal injection using a sclerosant (Fig. 103-45). With the patient under general anesthesia, injection with 5% sodium morrhuate or cow's milk¹⁵¹ has been performed successfully on an outpatient basis. About 90% of children can be treated successfully with a single four-quadrant sclerosant technique, but on occasion further sclerosis is necessary. Submucosal dissection or cauterization is also successful but may have a higher incidence of postoperative bleeding or stricture formation and usually requires a short period of hospitalization. The major objective in treating childhood rectal prolapse is to create a local extraperitoneal inflammatory process in the perirectal space. Morbidity is low and the long-term outcome is excellent.

PEDIATRIC LIVER

Tumors of the Liver

Primary hepatic tumors are rare in children and at least 60% to 70% are malignant.^{152,153} Table 103-12 reviews the incidence rates and types of hepatic tumors presenting during infancy and childhood. Pediatric hepatic tumors often manifest as asymptomatic abdominal masses discovered by parents or pediatrician. Symptoms related to the tumor, such as pain, hemorrhage, hypertension, and precocious puberty, are less frequent. Initial diagnostic imaging studies include plain abdominal radiographs and ultrasound to assist in early determination as to whether the mass is cystic or solid and whether calcifications are present. CT scan imaging and MRI remain definitive in the ability to discern anatomic characteristics of the mass and its relationship to adjacent structures. Most children require operative exploration for either definitive excision or incisional biopsy in lesions deemed unresectable.

Benign Tumors

Of all primary liver tumors of childhood, 30% are benign. The most common benign tumors are hemangiomas, hemangioendotheliomas, mesenchymal hamartomas, cysts, focal nodular hyperplasia, and hepatic adenoma. In most large series, hemangiomas constitute about 50% of the benign hepatic tumors observed.¹⁵⁴

Vascular Tumors. Infantile hepatic hemangiomas represent a clinically diverse spectrum of vascular endothelial anomalies. They are characterized by a phase of proliferative growth over the first year of life, with subsequent involution over several years. The International Society for the Study of Vascular Anomalies classifies vascular tumors into two categories based upon the presence or absence of GLUT-1, an erythrocyte-type glucose transporter protein expressed in the endothelium of the placenta and hemangiomas.¹⁵⁵ Therefore, hemangiomas are GLUT-1 positive, and other, more heterogeneous vascular anomalies such as vascular malformations are GLUT-1 negative. Most asymptomatic infantile hepatic hemangiomas are detected as incidental findings on diagnostic imaging studies performed for unrelated reasons. A smaller proportion will create symptoms of enlarging abdominal mass, progressive hepatic failure, high output cardiac failure due to shunting, thrombocytopenia, or hypothyroidism from excess production of type III iodothyronine deiodinase.¹⁵⁶

Figure 103-45. Four-quadrant injection of sclerosant into the rectal submucosa for the treatment of childhood rectal prolapse.

Most benign vascular lesions of the pediatric liver do not require operative management. Operative intervention is generally reserved for bleeding secondary to traumatic rupture symptoms not controllable with medical management. Treatment strategies remain highly individualized based upon the whether the lesions are focal, multifocal, or diffuse.¹⁵⁷ In the face of multifocal or diffuse disease associated with congestive heart failure and thrombocytopenia secondary to sequestration, medical treatment with corticosteroid therapy may be useful. More invasive procedures such as irradiation, selective hepatic arterial ligation, angiographic embolization, or hepatic transplantation remain useful in selected patients with uncontrollable symptoms. Chemotherapeutic agents, including recombinant alpha-interferon, low-dose vincristine, and cyclophosphamide, have been used for life-threatening vascular lesions. Hepatic resection is generally reserved for mass lesions of unknown diagnosis, ruptured vascular lesions with signs of active hemorrhage, or for symptomatic, locally resectable lesions.

Table 103-12 Incidence of Liver Tumors in Childhood

Tumor Type	Incidence Rate (%)
Benign	
Vascular tumors	13
Hemangioma	9
Hemangioendothelioma	4
Mesenchymal hamartoma	6
Focal nodular hyperplasia	2
Adenoma	2
Teratoma	2
Other	3
Malignant	
Hepatoblastoma	43
Hepatocellular carcinoma	23
Malignant mesenchymal tumor	4
Sarcoma	2
Embryonal cell carcinoma	2
Angiosarcoma	1

Hemangioendotheliomas are important vascular anomalies encountered in infants. The lesions vary in size from 1 cm to several centimeters in diameter and may be multiple (Fig. 103-46). Symptomatic neonates may present with an abdominal mass, hepatomegaly, and congestive heart failure. These infants may also experience spontaneous rupture and hemoperitoneum, with tachycardia, tachypnea, and hypovolemic shock. On examination, the infant may have other cutaneous hemangiomas visible on the skin. Affected infants may develop thrombocytopenia secondary to platelet sequestration in the vascular malformation (*Kasabach–Merritt syndrome*). CT scan imaging or MRI is diagnostic. Treatment is directed at controlling symptoms using medical management principles as discussed previously; however, hemangioendotheliomas tend to be more problematic than hemangiomas because of the tendency to occur during infancy and the more extensive, symptomatic nature of the lesions.

Figure 103-46. Selective visceral angiogram demonstrating large hepatic vascular malformation in a neonate with congestive heart failure. This finding is consistent with a bilobar hemangioendothelioma.

Mesenchymal Hamartomas. Approximately one-third of benign hepatic tumors in children are mesenchymal hamartomas. A mesenchymal hamartoma is often quite large and typically presents within the first year of life as an asymptomatic, solitary abdominal mass. CT scan imaging or MRI studies are usually diagnostic and show a solid mass that may have cystic components within the liver parenchyma. Definitive diagnosis may require open tissue biopsy, and the therapy of choice is complete excision, although spontaneous involution has been described. Simple enucleation may be adequate because these tumors tend to be well circumscribed. On occasion, formal hepatic resection may be required.¹⁵⁸ Recurrence is low after adequate resection.

Focal Nodular Hyperplasia. This tumor occurs primarily in female children and in adults and may be associated with the use of oral contraceptives or focal hepatic injury. Focal nodular hyperplasia is usually a well-defined, solitary mass that has characteristic findings on CT scan imaging. Open or percutaneous biopsy may be required to differentiate the lesion from hepatic adenoma. This lesion results from a focal inflammatory response of normal hepatic parenchyma surrounded by areas of micronodular fibrosis and cirrhosis. Operative management is generally unnecessary unless there is a question of diagnosis or active hemorrhage from the lesion.

Hepatic Adenoma. Adenomas are rare in infants and children and constitute less than 5% of all benign hepatic lesions in the pediatric age group. There is an association between the use of oral contraceptives, exogenous anabolic steroid use, and glycogen storage disease type I (von Gierke disease). These tend to be large, solitary lesions located in the right hepatic lobe. The typical presentation is an asymptomatic abdominal mass, although symptoms are seen more commonly than with focal nodular hyperplasia. About 20% to 25% of patients with hepatic adenoma present with hemoperitoneum from tumor rupture. On histologic examination, these lesions are composed of normal hepatocytes without evidence of dysplasia. Operative therapy is usually directed at either making definitive diagnosis or treating hemorrhage. Enucleation or local resection is adequate and recurrence rates are low.

Hepatic Cysts. Congenital cysts of the liver may be either solitary or multiple. These cysts are thought to result from failure of the intralobular or interlobular biliary ducts to fuse during development. They may be lined with cuboidal, columnar, or squamous epithelium.¹⁵⁹ The presence of multiple hepatic cysts is associated with polycystic kidney disease, and development of progressive hepatic and renal failure is a potential problem with this disease. The majority of children with hepatic cysts are asymptomatic. Adjunctive diagnostic imaging, including ultrasound and CT scan imaging, may be useful.

Asymptomatic congenital hepatic cysts do not require surgical therapy. Operative therapy is reserved for symptomatic cysts. Resection or drainage by marsupialization or hepaticocystenterostomy may be required. If patency to the biliary tract is present on contrast injection study of the cyst, internal

drainage is necessary.

The differential diagnosis includes hydatid disease of the liver, which is suggested by calcification and loculation of the cyst wall. Hydatid disease can be diagnosed using specific serologic tests, which is an important surgical consideration prior to exploration. Patients with echinococcal cysts should be treated with mebendazole and undergo cyst injection with hypertonic saline or other scolicidal agents into the parent cyst before surgical excision. Careful control of the cyst contents is required during echinococcal cyst excision or marsupialization.

Teratomas. Teratomas of the liver are exceedingly rare and have potential for harboring immature elements capable of transforming into malignancy. Surgical resection on discovery is recommended.

Malignant Tumors

Two thirds of childhood hepatic tumors are malignant, with hepatoblastoma constituting half of the malignancies, followed by hepatocellular carcinoma, malignant mesenchymal tumors, and sarcoma.¹⁵² Malignant hepatic tumors are fortunately rare, and effective treatment requires a multidisciplinary approach that is best achieved in an experienced pediatric center.

Hepatoblastoma. Most hepatoblastomas are discovered in children younger than 2 years. There is a 2:1 male-to-female predominance. Hepatoblastomas usually are found as either an asymptomatic abdominal mass or symptoms of gastrointestinal obstruction from extrinsic compression by the mass. There is an association of hepatoblastoma in patients with Beckwith–Wiedemann syndrome and hemihypertrophy. On examination, a firm, palpable upper abdominal mass is notable. Obstructive jaundice is unusual. More than 90% of children with hepatoblastoma have elevated levels of alpha-fetoprotein, which is useful serum tumor marker for postoperative surveillance. In few instances, children have initial symptoms and signs of excess androgen secretion, including virilization and precocious puberty. Diagnostic imaging with CT scan imaging or MRI is essential to evaluate the extent of the tumor and evaluate for metastatic disease (Fig. 103-47).

Most children presenting with hepatoblastoma initially have unresectable disease. In the absence of metastatic disease, however, an aggressive surgical approach is used. Cure and long-term survival with hepatoblastoma requires complete surgical excision of the primary lesion. Therefore, localized, resectable tumors usually are excised by formal hepatic lobectomy or extended trisegmentectomy. Children with hepatoblastomas considered initially unresectable or with metastatic disease should undergo percutaneous or incisional biopsy to confirm the histologic diagnosis, followed by multiagent chemotherapy to reduce the size of the primary tumor and control metastases.^{160,161} Delayed resection is appropriate if enough functional, normal hepatic parenchyma remain after resection. More than half of the patients who initially have unresectable hepatoblastoma can be rendered disease-free with the combination of chemotherapy and subsequent surgery. Cure rates for hepatoblastoma range from 60% to 80% if histologically clear margins and no metastatic disease are present. All patients with hepatoblastoma, regardless of stage, receive chemotherapy after resection. Unfortunately, cure cannot be expected in children treated with chemotherapy and radiation therapy alone without complete surgical resection.

Figure 103-47. Computed tomographic scan of the abdomen demonstrating an infant with hepatoblastoma of the right hepatic lobe.

Hepatocellular Carcinoma. Hepatocellular carcinoma is significantly more common in adults but is occasionally seen in older children and adolescents. There is a male predilection (2:1) and, except for

the age at diagnosis, the clinical presentation is similar to that for hepatoblastoma. Children with hepatocellular carcinoma are more likely to have jaundice and abnormal liver enzymes. The high association of cirrhosis in adults (80%) is not seen in children with hepatocellular carcinoma; only 5% of children develop hepatocellular carcinoma in the background of cirrhosis. An increased risk of hepatocellular carcinoma is seen in children with Beckwith–Wiedemann syndrome, hemihypertrophy, von Gierke disease, hepatitis B, and Fanconi syndrome. Exposure to oral contraceptives, anabolic steroids, and some chemotherapeutic agents also has been associated with hepatocellular carcinoma. This malignancy carries a poor prognosis with an overall survival rate of 10% to 20% despite aggressive surgical resection and multiagent chemotherapy. A histologic variant, fibrolamellar hepatocellular carcinoma, carries a more favorable prognosis. As with hepatoblastoma, complete surgical resection with clear histologic margins is necessary for long-term survival and cure. In the absence of metastatic disease, unresectable hepatoblastoma or hepatocellular carcinoma in children has been successfully treated by orthotopic liver transplantation. Review of data from the United Network for Organ Sharing database demonstrates good long-term survival for both hepatoblastoma (66% 10-year survival) and hepatocellular carcinoma (58% 10-year survival) treated with liver transplantation.¹⁶²

Malignant Mesenchymal Tumors. These rare hepatic malignancies occur in children 5 to 10 years of age; initial signs are fever, pain, and an abdominal mass, which is usually quite large on diagnosis and may have both solid and cystic components. Multidisciplinary treatment, including complete surgical resection, multiagent chemotherapy, and radiation therapy, is required for cure. In general, the prognosis of primary malignant mesenchymal tumors of the liver remains poor.

Sarcomas. Children may rarely have a primary sarcoma of the liver. Embryonal rhabdomyosarcoma of the biliary tract is distinctly unusual. It may manifest with obstructive jaundice attributable to both extrinsic and intrinsic biliary tract obstruction. Undifferentiated, embryonal sarcoma of the liver has also been described. Angiosarcoma developing in the liver may be associated with exposure to toxins such as arsenic. Aggressive surgical resection may be required, but long-term survival is uncommon. Despite radical surgery, chemotherapy, and radiation therapy, the prognosis and long-term survival of children with these malignancies remain poor, and data regarding effective drug regimens are limited.^{163,164}

Liver Resection

Operative principles and techniques for hepatic resection are discussed elsewhere in this book. Several unique issues in the safe performance of hepatic resection in children should be emphasized.¹⁶⁵ Contemporary management of hepatic resection for tumors in children requires adequate preoperative assessment and the liberal use of intraoperative monitoring techniques. The circulating blood volume of an infant or a child is less compared to an adult, and children are sensitive to compression of the inferior vena cava causing decreased venous return to the right heart. Blood must be available for transfusion and adequate intravenous access is essential. Resection can be performed through either a subcostal incision or a right thoracoabdominal incision; in general, the ability to perform the operation safely should not be limited by the size of the incision. In children, the right and left hepatic veins are difficult to control near the inferior vena cava because of their short lengths, and intraparenchymal control from an anterior approach may be safer (Fig. 103-48). Resection may be performed using total hepatic vascular isolation by controlling the hepatic and portal inflow, the suprahepatic inferior vena cava, and the suprarenal inferior vena cava caudal to the liver. When extrahepatic biliary duct reconstruction is required, T-tube drainage is not routinely performed given the small diameter of the ducts in most children.

Figure 103-48. A: The hepatic veins in infants and children may be extremely short, making extrahepatic control impossible or dangerous. B: Intrahepatic control of the hepatic veins via an anterior approach may be safer in infants and children.

Hepatic Infections

Hepatic infections are generally rare in the pediatric population, and their management is similar to that used in adults. An important issue is the development of hepatic abscess in an immunocompromised child and, in particular, the association of chronic granulomatous disease with pyogenic hepatic abscess formation.

Pyogenic Abscess

The most common cause of pyogenic liver abscess before the advent of antibiotic therapy was perforated appendicitis. Now the most common causative factor in the development of pyogenic hepatic abscess in children with chronic granulomatous disease and other causes of immunosuppression.¹⁶⁶ Chronic granulomatous disease is an inherited disorder characterized by a defect in oxidative burst-mediated bacterial killing by neutrophils. These children develop skin, soft-tissue, and solid organ abscesses. A significant number of children with pyogenic liver abscesses have chronic granulomatous disease or other inherited/acquired immunodeficiency states. Liver abscesses are infrequently seen as a complication of umbilical vein catheterization, omphalitis, biliary tract disease, and hepatobiliary operations.

Patients with pyogenic liver abscess present with fever, jaundice, and leukocytosis. Hepatosplenomegaly and a tender liver may be found on physical examination. Diagnostic imaging with ultrasound, CT scan imaging, or MRI is useful. Common responsible organisms include staphylococcal species, streptococcal species, and *E. coli*. Gram-negative organisms and anaerobic bacteria are becoming increasingly prevalent. Treatment involves the use of broad-spectrum antibiotics. Large abscess cavities may require image-guided percutaneous drainage to expedite resolution of sepsis. Currently, few hepatic abscesses require open operative drainage. The outcome is dependent upon the underlying disease process. Recovery from the abscess is predictably good following adequate antibiotic therapy and drainage when necessary.

Amebic Abscess

Amebic abscess of the liver is uncommon in the United States, but it is endemic to areas of Central and South America. It is caused by infection with the parasite *Entamoeba histolytica*. Children with amebic dysentery develop hepatic infection as the parasite travels through the portal circulation. Patients have a history of chronic illness, fever, and abdominal pain. Examination typically demonstrates a tender right upper quadrant. Infection can be confirmed by a serum antibody test, and amebic abscess can be demonstrated by ultrasound or CT scan. Spontaneous rupture of amebic abscess is reported in as many as 10% of patients in some series.¹⁶⁷ The treatment of choice is the antibiotic metronidazole. Surgical resection or drainage of amebic liver abscess is typically not required for resolution.

PEDIATRIC BILIARY TRACT

Common biliary tract problems including infectious, inflammatory, and gallstone-related problems are managed similarly in both children and adults, and the management principles are discussed elsewhere in this text. Two congenital problems of the biliary tract, namely, biliary atresia and congenital cystic disease of the biliary tract (choledochal cyst), are somewhat unique to infants and children in presentation and management and are reviewed in the following discussion.

Embryology

The fetal liver and biliary tract develop between weeks 4 and 10 of gestation, representing the fusion of an endodermal foregut diverticulum with a mesodermal component from the septum transversum. The hepatocytes are derived from cords of endodermal cells in the hepatic diverticulum and ultimately give rise to the hepatic sinusoidal endothelium. The proximal hepatic diverticulum gives rise to the extrahepatic biliary tract, including the gallbladder, cystic duct, and common bile duct. As the intrahepatic and extrahepatic ductal systems develop, they unite to form a connected, arborizing system of cords composed of primitive ductular epithelial cells. These epithelial cells assume tubular configuration with ductal patency established between weeks 6 and 12 of gestation. Bile flow from the hepatocytes and into the biliary duct system is apparent by the beginning of the second fetal trimester.

This embryologic sequence appears to take place normally in infants who develop biliary atresia. In fact, the term *biliary atresia* does not reflect embryologic atresia resulting from failure of recanalization of the biliary tree. Rather, biliary atresia is caused by an uncontrollable inflammatory process that produces progressive obliteration of the normally developed extrahepatic biliary tract.

Biliary Atresia

Anatomy

7 The overall incidence rate of biliary atresia is about 1 in 8,000 to 12,000 live births and is the most common cause of chronic cholestasis in infants and children as well as the most frequent indication for pediatric liver transplantation.¹⁶⁸ Extrahepatic biliary atresia must be differentiated from biliary hypoplasia. Biliary hypoplasia describes a diminutive but patent biliary system and can result from many underlying situations such as neonatal hepatitis and α_1 -antitrypsin deficiency. Biliary hypoplasia involves both intrahepatic and extrahepatic ductal systems.

Microscopic Anatomy. Biliary atresia is characterized by replacement of the extrahepatic biliary tract with dense, fibrous inflammatory tissue. In most cases, complete obliteration of the extrahepatic biliary tract, including the gallbladder, occurs. There appears to be gradual progression of the inflammatory process with advancing age. The common hepatic duct and common bile duct are almost uniformly obliterated by the inflammatory process. Few or absent patent ductal remnants and an absence of portal inflammation may be associated with a less favorable prognosis.¹⁶⁹ Intraoperative evaluation for duct patency by frozen section analysis has historically been used help guide the extent of proximal resection at the porta hepatis; however, this is no longer in widespread use. The presence of bile ducts at the porta hepatis with diameter greater than 150 μm has been reported to be associated with postoperative bile flow in up to 90% to 95% of cases.¹⁷⁰

Histologic features of biliary atresia reflect hepatic parenchymal injury. Neocholangiogenesis, or biliary duct proliferation of disorganized and nonpatent ducts within the liver, is considered highly suggestive but not specific for biliary atresia. Other findings include bile pigment deposition throughout the liver. Characteristic early findings in biliary atresia include evidence for acute inflammation with neutrophil predominance in the periportal regions. Older infants and children typically have chronic inflammatory changes with considerable fibrosis. Periportal bridging fibrosis is commonly seen in intermediate stages of the disease. Ultimately, progressive biliary atresia leads to intractable cirrhosis. Nearly all patients with biliary atresia have histologic evidence of liver injury. The severity and extent of liver damage may be the most important predictor of long-term outcome and survival in biliary atresia.

Pathophysiology

Despite numerous investigations, the mechanism causing biliary atresia remains unknown. The current, widely accepted concept is that the normally developed biliary tract undergoes inflammatory sclerosis and subsequent obliteration. This process appears to occur during the first few weeks to months of life. Infants who develop biliary atresia are rarely jaundiced at birth, and biliary atresia is either rare or nonexistent in fetal autopsy studies. Clinical data are consistent with the fact that biliary atresia appears to be a progressive, dynamic inflammatory response that is acquired during the perinatal period and targets the extrahepatic biliary tract. Early establishment of biliary drainage via portoenterostomy within the first 2 to 4 months of age may be associated with reversal of liver injury and subsequent long-term survival. Conversely, infants operated on after 120 days of life typically have obliterated bile ducts. Neonatal biliary atresia shares some clinical and morphologic features of sclerosing cholangitis in adults. Data supporting an infectious etiologic agent and, in particular, reoviruses, rotaviruses, and hepatitis C, have been reported and may play a role in some cases. In addition, other noninfectious stimuli may trigger an inflammatory response directed at the neonatal extrahepatic bile duct.¹⁷¹ The actual mechanism may reflect a stereotypical inflammatory response initiated by a variety of different stimuli that is ultimately directed preferentially against the neonatal bile duct.

Figure 103-49. A: Normal scan using p-isopropyl acetanilidoiminodiacetic acid (PIPIDA) as the hepatobiliary scanning agent. At 45 minutes, isotope is clearly visible in the liver (L) and the intestine (I). B: Scan after phenobarbital administration in infant with biliary atresia. Even after 8 hours, isotope is apparent only in the liver and the urinary bladder (UB). C: Patient with cholestatic jaundice. At 65 minutes, isotope is visible in the liver (L) and the intestine (I). Hepatocyte uptake is variable but usually decreased or normal, whereas excretion into the gut is predictably present with cholestatic jaundice or hepatocellular disease.

Clinical Presentation and Diagnosis

The cardinal sign of biliary atresia is progressive neonatal jaundice during the first few weeks of life. Dark urine and acholic stools are expected findings. Progressive hyperbilirubinemia produces clinical jaundice around 2 to 4 weeks of age. The physical examination is generally unremarkable except for jaundice and possibly mild hepatomegaly. Alagille syndrome, which presents with neonatal jaundice, can usually be distinguished from biliary atresia on physical examination. Children with Alagille syndrome have biliary hypoplasia and distinctly abnormal facies, growth retardation, vertebral defects, and pulmonic stenosis.

A characteristic laboratory finding is conjugated hyperbilirubinemia consistent with obstructive jaundice. A direct fraction of bilirubin greater than 50%, or greater than 2 mg/dL, in an infant requires prompt investigation. Mild elevation of hepatic transaminases is commonly seen. The alkaline phosphatase is significantly elevated, often in the range of 500 to 1,000 IU/L. There are no specific biochemical markers for biliary atresia, as these serum profiles can be seen in other causes of neonatal cholestasis. Late findings in biliary atresia include failure to thrive, feeding intolerance, stigmata of portal hypertension, and fat-soluble vitamin deficiency.

Table 103-13 is a partial list of the causes of neonatal cholestatic syndromes. Neonatal physiologic jaundice is commonly encountered. This condition is self-limited once the glucuronyl transferase system matures, allowing the hepatocytes to conjugate bilirubin efficiently. Because of the numerous causes of neonatal jaundice and the relative infrequency of biliary atresia, a delay in diagnosis is common. Given the age-sensitive nature of biliary atresia and the improved outcome in younger infants, the diagnostic workup should be expedient.

ETIOLOGY

Table 103-13 Causes and Associations of Neonatal Cholestasis

Congenital Infectious Causes
Cytomegalovirus ^a
Rubella virus ^a
Herpes virus
Hepatitis virus B ^a
Echovirus 14, 19
Coxsackievirus B
Toxoplasmosis
Syphilis
Genetic Associations
Galactosemia
Tyrosinemia
Congenital fructose intolerance
Alpha ₁ -antitrypsin deficiency
Cystic fibrosis
Niemann–Pick disease
Trisomy 17, 18, 21
Turner syndrome
Menkes syndrome
Zellweger syndrome
Polysplenia syndrome ^b
Miscellaneous Associations
Hemolytic disease
Bacterial sepsis
Pyelonephritis
Total parenteral nutrition (prolonged)
Congestive heart failure
Hypoplastic left heart syndrome
Necrotizing enterocolitis, gastroschisis, omphalocele
Neonatal hypopituitarism
Inspissated bile syndrome (without hemolysis) neonatal shock, respiratory distress syndrome, acidosis

^aRarely associated with biliary atresia.

^bFrequently associated with biliary atresia.

Figure 103-50. The essential features of the portoenterostomy for biliary atresia include appropriate mobilization (A) and transection (B) of the fibrous biliary tract remnant. C: Creation of a Roux-Y jejunal conduit with biliary enteric anastomosis completes the procedure.

Radioisotope Scanning. Pertechnetate 99 m–iminodiacetic acid (^{99m}Tc -IDA) analogues are widely used for hepatobiliary imaging and provide the basis for a sensitive and specific test for biliary atresia. The sensitivity of this diagnostic examination for biliary atresia can be 100%, with a specificity of 94%.¹⁷² To improve sensitivity, infants are administered oral phenobarbital (5 mg/kg daily) to induce hepatic microsomal enzymes and increase hepatocyte processing of ^{99m}Tc -IDA. Both hepatic uptake of radionuclide and excretion into the gastrointestinal tract are evaluated over a timed interval. Infants with primary hepatocellular disorders characteristically have impaired hepatocyte uptake of radionuclide, whereas normal infants and infants with biliary atresia have prompt uptake. Normal infants excrete the isotope rapidly into the gut through the biliary tract. In biliary atresia, there is no excretion into the gut because of the obliteration of the extrahepatic bile ducts (Fig. 103-49). The hepatobiliary scanning is a rapid test that can be performed simultaneously with other diagnostic examinations, for example, ultrasound. This test reliably identifies infants with choledochal cyst as well.

Other Diagnostic Tests. Several other diagnostic tests are of interest in the workup of an infant with conjugated hyperbilirubinemia in whom obstructive jaundice is suspected. MRI cholangiography is emerging as a sensitive, specific examination for the identification of extrahepatic anatomy. The important management principle is that prompt operative exploration, liver biopsy, and cholangiography should be performed in any infant in whom biliary atresia is suspected. An aggressive approach is warranted in that unnecessary delay in definitive drainage may lead to a less favorable outcome.

Ultrasound. A standard examination of the jaundiced infant is a comprehensive abdominal ultrasound, with particular attention given to the liver and the biliary tract. The most common ultrasonographic finding in biliary atresia is a diminutive or absent gallbladder without associated intrahepatic duct dilatation. Biliary tract obstruction from a choledochal cyst also can be reliably identified by ultrasound. Other rare causes of extrahepatic biliary duct obstruction are associated with proximal duct dilatation.

Figure 103-51. Several types of conduits have been used for biliary drainage following portoenterostomy. There are relatively few data to help in selecting from among them, and current trends emphasize simplicity. These are the three most commonly used conduits. The primary importance of this issue is that the reoperative surgeon must be familiar with the anatomic variations.

Liver Biopsy. Because the histologic findings in biliary atresia are not specific, about 20% to 25% of infants who undergo percutaneous liver biopsy remain undiagnosed. Liver biopsy is often performed in conjunction with the workup of conjugated hyperbilirubinemia following hepatobiliary scanning and ultrasonography, but in the setting of biliary atresia, it has limited utility. The histologic examination of a percutaneous liver biopsy is probably most helpful in diagnosing nonoperative causes of neonatal jaundice, thus avoiding anesthesia and operative exploration.

Alpha₁-Antitrypsin Deficiency. Alpha₁-antitrypsin deficiency is perhaps the single most important medical condition that may be difficult or impossible to differentiate from biliary atresia. All jaundiced infants should have plasma alpha₁-antitrypsin levels determined before operative exploration for suspected biliary atresia. Infants with alpha₁-antitrypsin deficiency do not benefit from operative

exploration or portoenterostomy.

Treatment

Infants with biliary atresia require surgical therapy as the initial management intervention. Medical therapy is directed to the postoperative management of the chronic liver disease. The use of sequential surgical treatment, using portoenterostomy in infancy and orthotopic liver transplantation for children with progressive hepatic failure, provides improvement in overall survival.^{173,174} Limited organ availability and a higher rate of perioperative complications limit primary liver transplantation for most infants with biliary atresia younger than 1 year. In the rare instance of unrecognized biliary atresia in an older child with established hepatic dysfunction, primary orthotopic liver transplantation may be a reasonable option.

Portoenterostomy. The recommended initial procedure for the treatment of biliary atresia is portoenterostomy. Before the development of portoenterostomy in Japan by Morio Kasai during the late 1950s, all infants with biliary atresia died of chronic liver disease and cirrhosis. Current management dictates that operative exploration and portoenterostomy be performed promptly. Early intervention by portoenterostomy to provide biliary drainage has been proposed to arrest or reverse the parenchymal liver injury, but the point at which the liver injury becomes irreversible remains unknown. From a clinical standpoint, most long-term success with portoenterostomy alone appears to be achieved in infants younger than 2 to 3 months, whereas infants older than 3 to 4 months appear to have a less favorable prognosis. Portoenterostomy for this “late” group has been reported successfully in approximately one-third of infants, however, and should be considered a potential alternative in the absence of available liver transplant donors.¹⁷⁵

The initial approach to the infant with suspected biliary atresia is to perform an operative cholangiogram. If the diagnosis is confirmed, a portoenterostomy is constructed (Fig. 103-50). To maximize the potential for effective biliary drainage with portoenterostomy, several technical caveats are worthy of mention. An open liver biopsy is routinely performed to document the state of parenchymal injury. The cholangiogram is generally attempted through the gallbladder. In the 10% to 15% instance of a patent distal biliary tree, treatment still requires portoenterostomy. A nonpatent, fibrous cord rather than a normal common bile duct is found in the hepatoduodenal ligament. This cord is dissected free proximally to the level of the porta hepatis between the portal vein bifurcation. The fibrous remnant is sharply transected at this level to preserve any patent bile ducts. A short, 15- to 25-cm retrocolic, jejunal Roux-Y limb is constructed. There has been no clear advantage with longer or modified conduits with intussusception-type antireflux valves in the prevention of cholangitis.^{176,177}

Previously, some surgeons preferred to exteriorize the biliary conduit (Fig. 103-51). With an exteriorized biliary conduit, postoperative bile flow is directly visible. The diverting stoma must be closed, however, and there is potential to develop parastomal variceal hemorrhage from progressive portal hypertension. In addition, fluid and electrolyte losses from the biliostomy can be significant, and there are no reported survival differences between patients with exteriorized and closed biliary conduits following portoenterostomy. Because many of these infants may ultimately require liver transplantation, there is a trend toward using a simple, closed biliary conduit with portoenterostomy. Therefore, the use of a stoma to divert the bile flow in the Roux limb has been largely abandoned.

Figure 103-52. Classification of choledochal cyst.

Results and Complications. Following portoenterostomy, bile flow occurs in about 66% to 75% of all infants when operated on at less than 60 days of age; however, establishment of bile flow may take weeks to months. The probability of bile flow appears related to age at the time of operation.

Cholangitis is a constant concern and an important postoperative problem after portoenterostomy. The clinical signs include fever, leukocytosis, and decreased bile flow in the absence of other systemic illness. All patients are at risk for the development of postoperative cholangitis, but reported postoperative rates of cholangitis are 40% to 50%. Cholangitis following portoenterostomy is characterized by a systemic inflammatory response and may be associated with progressive liver injury. Treatment is generally intravenous fluid resuscitation and broad-spectrum antibiotics. Occasionally, steroids or other antiinflammatory agents may be helpful, whereas reoperation or endoscopic revision of the portoenterostomy usually is not.¹⁷⁸ In an effort to determine the optimal treatment of infants with biliary atresia, a group of investigators have formed the Biliary Atresia Research Consortium (BARC).¹⁷⁹ The primary objectives of the consortium are to establish a clinical database and tissue repository. A retrospective BARC study of 104 children with biliary atresia treated in the United States demonstrated that at 2 years of age, 58 patients were alive with their native liver and 42 had undergone liver transplantation.¹⁸⁰ Data from the United Kingdom demonstrated improved measurable outcomes in

children with biliary atresia treated with Kasai portoenterostomy by regionalization of care to three centers in the UK health care system.¹⁸¹

Figure 103-53. An anomalous, extramural junction between the distal common bile duct and the pancreatic duct is characteristic of type I choledochal cyst. **A:** Schematic depiction of this anatomy. **B:** Operative cholangiogram from a patient with a long extramural common channel. It has been suggested that the long common channel may allow reflux of pancreatic secretions into the common bile duct resulting in inflammation and proteinase-mediated injury to the common duct, possibly contributing to the development of the cyst itself. CBD + PD, common bile duct and pancreatic duct; Duod, duodenum; PD, pancreatic duct.

Nearly all patients with biliary atresia have residual liver injury. Hepatic synthetic failure, portal hypertension with esophageal variceal bleeding, hypersplenism, and fat-soluble vitamin deficiencies can be problematic. Most institutions report 5-year survival rates between 30% and 50% for portoenterostomy alone. About 25% to 35% of patients undergoing a portoenterostomy survive more than 10 years without liver transplantation. The remaining two-thirds of children with biliary atresia ultimately require liver transplantation for survival. Although the failure rate for portoenterostomy is high, the possibility of long-term success is notable. In addition, the limited availability of infant donor organs and the technical limitations of liver transplantation in infants younger than 1 year make portoenterostomy an accepted initial treatment of biliary atresia in most centers.

Hepatic Transplantation. Hepatic transplantation is discussed in detail elsewhere in this text. For biliary atresia, transplantation offers a means of long-term survival in children with failed portoenterostomies. The current 5-year survival of children with biliary atresia who undergo liver transplantation ranges from 75% to 94.4%.^{182,183} In addition, with the use of reduced-size cadaveric donor livers as well as living-related donor livers, the mortality rate for infants on transplant waiting lists may be decreasing. Indications for liver transplantation in biliary atresia include progressive hepatic failure despite portoenterostomy, growth retardation, and complications of portal hypertension. It is important to consider the consequences of life-long immunosuppression in these children, including the risks of infection and treatment-related malignancy.

Congenital Choledochal Cystic Disease of the Biliary Tract

Anatomy

The anatomic description and classification scheme for choledochal cystic disease initially proposed by Alonso-Lej et al. in 1959 and modified by Todani et al. are illustrated in Figure 103-52.^{184,185} The most frequently encountered are type I cysts, accounting for approximately 85% to 90% of the lesions in most series. Type I cysts are characterized by fusiform dilatation of the entire common bile duct with only mild dilatation of the common hepatic duct; the intrahepatic ducts are normal. Variations are common, and biliary atresia is occasionally seen in association with choledochal cystic disease.

Type I cysts are generally quite large and often cause displacement of neighboring viscera. The fusiform dilatation usually begins at the origin of the common bile duct, generally sparing the common hepatic ducts. The distal common bile duct is diminutive and typically is distorted mechanically by the large cyst, leading to the common clinical presentation of obstructive jaundice. The junction of the distal common bile duct and the pancreatic duct is not within the normal intramural duodenum but rather is extrinsic and proximal to the duodenal wall and the sphincter of Oddi (Fig. 103-53). It remains unknown whether the configuration of a long, extramural common channel allows greater pancreatic secretion reflux into the common bile duct.

Microscopic examination of the choledochal cyst wall reveals that the normal biliary epithelium is absent or replaced by abnormal and occasionally dysplastic columnar epithelium. The cyst wall has normal smooth muscle with variable degrees of inflammation and fibrosis. The exception to this common histologic characteristic is the type III cyst, which is generally lined by normal duodenal mucosa. Choledochal cysts tend to have less inflammation in infancy and early childhood. In contrast, there is well-established inflammation involving the cyst and surrounding structures in the hepatoduodenal ligament in adolescents and adults.

Figure 103-54. Typical ^{99m}Tc -N-substituted-2,6-dimethylphenyl carbamoylmethyl iminodiacetic acid (HIDA) scan from a child with a type I choledochal cyst. Images were made in 5 minutes (A), 30 minutes (B), and 3 hours (C), after isotope injection. The isotope is retained within the choledochal cyst more than 24 hours, and the pattern of hepatocyte uptake is normal.

Pathophysiology

The mechanism for the development of cystic lesions of the biliary tract is unclear. Choledochal cysts have been identified accurately by prenatal ultrasound, and it appears likely that these lesions represent abnormalities in the developing biliary tract. Several hypotheses for the development of choledochal cyst have been proposed. Whether the cystic dilatations result from abnormal recanalization of the primitive bile duct cords or from inflammation caused by reflux of pancreatic secretions into the common bile duct remains unknown. The pathophysiology of choledochal cyst is that of obstructive jaundice. The obstruction may be primarily the result of mechanical outflow obstruction of a diminutive distal common bile duct with a dilated choledochal cyst. Alternatively, a large inflammatory cyst can cause obstruction of the biliary tract and of neighboring viscera by extrinsic compression. When discovered during infancy, obstructive jaundice is usually the initial clinical finding. The liver injury is typically reversible, and progression to biliary cirrhosis is rare. The exception to this situation is type V disease, which is associated with a high incidence of hepatic fibrosis.

Other initial clinical situations include cholelithiasis and acute bacterial cholangitis secondary to diminished bile drainage. Children with type III cysts may have acute pancreatitis. Infrequently, extrinsic compression of the portal vein by a large choledochal cyst may produce symptoms and signs of portal hypertension. Abdominal pain and tenderness following minor injury may lead to an incidental diagnosis of choledochal cyst on imaging studies.

Carcinoma of the biliary tract occurs in about 3% to 5% of patients with choledochal cyst. The number of reported cases remains small in the literature, but the incidence for biliary tract neoplasm is about 1,000 times that of the normal population.¹⁸⁶ Patients with choledochal cyst are at increased risk for the development of biliary tract carcinoma in adolescence or early adulthood. The dysplastic cyst epithelium may be susceptible to malignant change from chronic inflammation. Interestingly, there appears to be an increased risk of malignancy to develop anywhere in the biliary tract, gallbladder, or pancreas, and not just the choledochal cyst itself.¹⁸⁷ Therefore, current treatment emphasizes complete cyst excision or the cyst epithelium while providing adequate biliary drainage to prevent stasis and chronic inflammation. Infants and children treated for choledochal cyst should have long-term follow-up

for complications and potential malignancy.

Clinical Presentation and Diagnosis

Choledochal cysts present most commonly in infancy and early childhood with symptoms of obstructive jaundice. In older children and adults, the classic clinical triad of episodic abdominal pain, a palpable right upper-quadrant mass, and jaundice occurs in fewer than 50% of patients. Adults occasionally present with hepatomegaly or evidence of portal hypertension. The diagnosis in infants and most children can be confirmed by ultrasound examination and ^{99m}Tc -IDA imaging studies (Figs. 103-54 and 103-55). In older children, both MRI cholangiography and endoscopic retrograde cholangiopancreatography (ERCP) are highly sensitive and specific in confirming diagnosis. These lesions also are diagnosed incidentally during radiologic imaging studies for other reasons. Partial duodenal obstruction may lead to an upper gastrointestinal series that shows extrinsic compression from a large type I cyst or an intraluminal filling defect from a type III cyst. CT imaging of the abdomen following blunt trauma may lead to the diagnosis of biliary tract dilatation. Liver biopsy is not specific in choledochal cyst and has little diagnostic role other than to document the extent of liver injury.

Figure 103-55. Ultrasound image of a type I choledochal cyst (arrow; longitudinal image). The gallbladder (GB) is also shown.

Treatment

Type I Cysts. Initial operative strategy for a type I choledochal cyst is exploration and cholangiography, usually through the gallbladder, but occasionally contrast injection must be made directly into the common bile duct. Cholecystectomy is routinely performed. Historically, internal drainage procedures without cyst excision were widely used. These procedures have been associated with a higher rate of failure because of stricture, stone formation, pancreatitis, and cholangitis. In addition, there is the potential for the development of biliary tract carcinoma in the retained cyst. Therefore, internal drainage procedures without cyst excision have been abandoned. Current consensus for the surgical management of type I choledochal cyst is performance of primary cyst excision with Roux-Y hepaticojejunostomy reconstruction (Fig. 103-56). Primary cyst excision is accomplished routinely in infants and children.¹⁸⁸ For adults with severe inflammation and fibrosis, dissection may present problems resulting from inflammation and adhesion of the cyst wall to the hepatoduodenal ligament. A safer approach in this situation may be intramural cyst dissection and removal of the cyst wall epithelium, leaving the posteromedial outer cyst wall adjacent to the portal vein and hepatic artery intact.

Figure 103-56. The preferred operative treatment of type I choledochal cyst consists of primary total transmural cyst excision with Roux-Y hepaticojejunostomy.

Other Types of Cysts. Type II cysts are excised completely and the choledochotomy closed primarily. Type III choledochoceles require a transduodenal approach with either marsupialization or excision of the cyst. Care must be taken to identify the ampulla, and a formal sphincteroplasty may be required to ensure adequate drainage from the biliary tract and the pancreas. Type IV and V intrahepatic cystic diseases must be approached on an individualized basis. In general, unilobar or focal cystic disease can be either resected or drained with Roux-Y jejunostomy reconstruction. Bilobar intraparenchymal disease, particularly in the setting of hepatic fibrosis, may be difficult, if not impossible, to obtain complete, adequate drainage.

Complications and Outcome. The major complications associated with operative repair of choledochal cyst include cholangitis, stricture formation, choledocholithiasis, and development of biliary tract malignancy. A summary of the incidence of complications, mortality, and reoperation for the different procedures in 955 cases reported in the literature demonstrated a clear advantage for primary cyst excision in terms of morbidity and need for reoperation, and no significant increase in mortality occurred using this approach.¹⁸⁹ Subsequent to this analysis in 1975, internal drainage procedures without cyst excision have been essentially replaced by primary cyst excision with hepaticojejunostomy reconstruction. Currently, several series have reported excellent results with little or no mortality using total transmural excision of choledochal cysts.¹⁹⁰ Primary transmural excision with biliary tract reconstruction continues to be a safe and desirable operative approach for cystic lesions of the biliary tract.

PEDIATRIC PANCREAS

Disorders of the pancreas are uncommon in infants and children. Pancreatic disorders in children include congenital anatomic disorders, inflammatory pancreatitis, rare neoplastic lesions, and pancreatic endocrinopathies.¹⁹¹ Several significant issues are relative to the pancreatic problems in the pediatric age group, and a brief overview is presented in the following discussion.

Embryology

The fetal pancreas arises from the paired dorsal and ventral foregut diverticular buds during the sixth week of gestation. The dorsal pancreatic anlage gives rise to the body and tail of the pancreas as well as the main pancreatic duct. The ventral pancreatic anlage migrates 180 degrees to fuse with the dorsal gland, forming the uncinate process and the distal portion of the duct of Wirsung (Fig. 103-57). The independent ductal systems of the developing pancreatic anlage fuse. The dorsal (Santorini) duct opens directly into the duodenum, and this anatomy is persistent in 10% to 15% of normal subjects. The

ventral (Wirsung) duct opens into the duodenum by fusion with the common bile duct. Normally, the dorsal duct fuses with the ventral duct just to the right of the mesenteric vessels. Failure of the dorsal and ventral ducts to fuse normally leads to two separate pancreatic ducts, a condition known as *pancreatic divisum*. Occasionally, the ventral duct regresses and the entire pancreatic gland is drained by the accessory duct of Santorini.

Figure 103-57. A: Normal pancreatic ductal anatomy. B: Pancreas divisum. There is no communication between the duct of Wirsung and the duct of Santorini. The duct of Wirsung is short or absent. Most of the pancreas is drained by the duct of Santorini through the accessory papilla. This anatomy is found in about 10% to 15% of normal individuals.

Primitive duct cells of the pancreas give rise to both the acinar cells and the islet cells of the normal pancreas. Primary islet cells become apparent at week 8 of gestation within the interlobular tissue, with acini becoming visible shortly thereafter. The primary islet cells regress after the fifth month of gestation and are usually nonexistent by term. Secondary islet cells arise from centroacinar proliferation during the third month of gestation. These intralobular cells migrate out of the acini in which they were formed and develop into islets that remain connected to the duct by a thin cellular stalk (the tubule of Bensley).

Exocrine pancreatic anomalies generally arise from defective development during embryogenesis. The most common of these conditions is annular pancreas. The circumferential distribution of pancreatic tissue around the duodenum is thought to result from interrupted migration of the ventral pancreatic anlage. Less common defects include pancreatic ductal abnormalities, pancreatic duplications, heterotopic pancreatic tissue, and congenital agenesis of portions of the pancreas.

Acute Pancreatitis

Acute pancreatitis is often overlooked as a cause of abdominal pain in children; however, it is the most common disorder of the pancreas in both infants and children. Adult pancreatitis is often caused by either alcohol ingestion or gallstones. In contrast, 50% to 80% of cases in children, particularly adolescents, are posttraumatic or idiopathic in origin. An important clinical condition seen with moderate frequency is acute pancreatitis in the setting of immunosuppression, in particular, high-dose corticosteroids. Steroid-induced acute pancreatitis typically accounts for the third most common cause of pancreatitis in most children's hospitals. Other causes of acute pancreatitis include gallstones, CF, hyperlipidemia, juvenile diabetes mellitus, mumps, coxsackievirus infection, infectious mononucleosis, collagen vascular diseases, and anatomic lesions such as choledochal cyst. Medications significantly associated with acute pancreatitis include oral contraceptives, chlorothiazide, tetracyclines, azathioprine, and L-asparaginase. Valproic acid, an anticonvulsant useful in some children with seizure disorders, is associated with a particularly virulent form of acute necrotizing pancreatitis that may be life-threatening.

A child with acute pancreatitis presents with a history of midepigastri abdominal pain, anorexia, and emesis. On examination, the child usually has a tender abdomen with distention. Fever and leukocytosis are common. Serum amylase and lipase levels are elevated, although significant pancreatitis can occur despite a normal amylase level. Conversely, the lipase may be mildly elevated in the absence of clinical

symptoms or signs of acute pancreatitis. Ultrasonography and CT imaging of the abdomen are probably the most commonly used adjunctive diagnostic tests. CT imaging is particularly useful in demonstrating edema of the gland as well as evaluating for peripancreatic fluid collections. While usually deferred during the acute phase of pancreatitis, ERCP or MRI cholangiography may be useful to evaluate the hepatobiliary tract anatomy once the inflammatory process has resolved.

Treatment principles for childhood acute pancreatitis are not different from strategies used in adults. The vast majority of children have simple edematous pancreatitis. Hemorrhagic pancreatitis and necrotizing pancreatitis are distinctly unusual in this age group but can be seen in immunosuppressed patients. Therefore, initial therapy is designed to be supportive and nonoperative in approach. Endotracheal intubation and mechanical ventilation may be required. Intravenous fluid resuscitation, pancreatic rest by nasogastric tube decompression, analgesia, and TPN are provided. No clinical efficacy data are available to support the widespread use of anticholinergics or somatostatin analogues for acute pancreatitis in children. Operative intervention is reserved for complications of pancreatitis such as hemorrhage, infected pancreatic necrosis, or pancreatic pseudocyst.

Recurrent pancreatitis in a child usually is associated with an anatomic abnormality or specific physiologic problem. Following recovery from the acute inflammatory event, an aggressive diagnostic workup, including consideration of ERCP or MRCP to define ductal anatomy, should be performed. In particular, the presence of pancreas divisum with stenosis of the accessory papilla should be considered. Children with pancreatitis in the setting of cholelithiasis should undergo laparoscopic cholecystectomy after resolution of the pancreatitis.

Pancreas Divisum

Pancreas divisum occurs with failure of normal fusion between the dorsal and ventral pancreatic ducts. About 10% to 15% of normal persons have two separate pancreatic ducts, and up to 10% of asymptomatic persons undergoing ERCP have two complete ductal systems. The anatomic variant of pancreas divisum is not necessarily pathologic, but if the orifice of the accessory papilla is stenotic or obstructed, pancreatitis can occur.¹⁹² Approximately 25% of affected individuals are thought to be at risk for developing pancreatitis. Because pancreas divisum is characterized by a dominant dorsal duct system dependent on secretion through the accessory papilla, stenosis of the accessory (lesser) papilla is probably necessary to produce pancreatic symptoms. Most of the experience with surgical treatment of pancreas divisum is reported in adults. Successful surgical management of children presenting with recurrent pancreatitis secondary to accessory papilla stenosis with pancreas divisum also has been reported.¹⁹³

To diagnose pancreas divisum, ERCP is required. Endoscopic visualization of the major and accessory papillae is essential. Radiographic findings with pancreas divisum demonstrate a short or absent duct of Wirsung that does not communicate with the duct of Santorini (see [Fig. 103-57](#)). Definitive diagnosis of pancreas divisum is made by demonstrating two separate, parallel ductal systems.

Few pediatric patients with pancreatitis and pancreas divisum requiring operation have been reported. Most of these children were female patients who had a history of recurrent pancreatitis. The primary operative goal is to provide adequate drainage of the duct of Santorini by performing a sphincterotomy of the accessory duct. An open dorsal duct sphincterotomy appears to be more durable than endoscopic sphincterotomy. Some surgeons advocate sphincterotomy of the main papilla as well, but dorsal duct sphincterotomy alone appears effective in preventing acute pancreatitis associated with pancreas divisum. The reported surgical outcome in the limited number of children treated for pancreatitis associated with pancreas divisum is favorable.

Pancreatic Cysts

Pancreatic pseudocysts are uncommon in the pediatric age group and are usually the result of blunt traumatic abdominal injury or acute pancreatitis. Children typically present with abdominal pain, nausea, emesis, and weight loss. There may be a palpable midepigastriac mass on examination. Diagnosis usually is made with ultrasound or CT imaging of the abdomen. The serum amylase and lipase are usually elevated.

In children, many small asymptomatic pseudocysts regress spontaneously with resolution of the pancreatic inflammation. Larger or symptomatic pseudocysts may require drainage. Symptoms and potential complications of untreated pseudocysts include hemorrhage, infection, perforation, gastrointestinal or biliary tract obstruction, or, rarely, development of pancreaticoenteric fistula. The decision to use either external or internal drainage procedures for a pseudocyst depends on the status of

the pancreatic duct. In many centers, definitive external drainage of a large or symptomatic pseudocyst is performed with acceptable morbidity and mortality rates by an ultrasound- or CT-guided percutaneous approach.¹⁹⁴ Pseudocyst recurrence or persistent external drainage without resolution suggests significant pancreatic duct injury or complete ductal transection. Determination of whether a major pancreatic ductal injury is associated with a pseudocyst may be made by either percutaneous contrast injection of the pseudocyst or ERCP.¹⁹⁵ Pseudocysts associated with pancreatic duct injury may not resolve with percutaneous external drainage or endoscopic pancreatic duct stenting, so internal drainage procedures such as cystgastrostomy or cystojejunostomy with or without distal pancreatectomy may be required.¹⁹⁶

Epithelial cysts of the pancreas are rare in children. Congenital cysts are lined by epithelium and acinar tissue and are seen most commonly in the body and tail of the pancreas. They may be associated with other syndromes such as von Hippel–Lindau disease, which is characterized by hereditary cerebellar cysts, retinal hemangioma, and pancreatic cysts. Congenital pancreatic cysts are typically asymptomatic unless they are large enough to cause compression or obstruction of the stomach or colon. In the absence of trauma, spontaneous rupture of a pancreatic epithelial cyst is rare. Treatment is cyst excision or internal drainage into the stomach or the jejunum.

Other rare cystic lesions of the pancreas in children include retention cysts. These cysts result from chronic ductal obstruction. They are characteristically lined by epithelium unless inflammatory obliteration has occurred. Enteric duplication cysts of the stomach or the duodenum can also be associated intimately with the pancreas and communicate with the pancreatic duct. Treatment of both retention cysts and enteric duplication cysts either within or associated with the pancreas includes excision, occasionally internal drainage, and, if necessary, distal pancreatectomy. Not all pancreatic cysts in children can be uniformly considered benign. Suspicious lesions should be investigated thoroughly and biopsy performed. Cystadenoma, cystadenocarcinoma, and rhabdomyosarcoma associated with a pancreatic cyst have been reported. These neoplasms are treated by anatomic pancreatic resection following histologic confirmation on biopsy.

Pancreatic Neoplasms

Childhood malignant neoplasms of the pancreas are uncommon. Typically, pancreatic malignancy in childhood is found on discovery of an asymptomatic abdominal mass. Infrequently, the lesion may be found incidentally or during a diagnostic imaging workup for abdominal trauma. Jaundice may occur with a lesion in the pancreatic head causing common bile duct obstruction. The most frequently encountered lesions include islet cell carcinoma and adenocarcinoma. The treatment of choice for localized malignant neoplasms of the pancreas is surgical resection.¹⁹⁷ Pancreaticoduodenectomy in children can successfully control some malignancies of the pancreatic head. To promote adequate nutrient absorption and growth, children undergoing pancreaticoduodenectomy should be considered for oral pancreatic enzyme replacement and fat-soluble vitamin supplementation.¹⁹⁸

Two pancreatic neoplasms seen in childhood and adolescence deserve further discussion. The *papillary cystic neoplasm* of the pancreas occurs predominantly in younger female children, is typically slow growing with low malignant potential, and is highly curable with surgical resection.¹⁹⁹ This tumor is thought to be a neoplasm of the ductuloacinar primordial cells of the pancreas. The other lesion is the *pancreatoblastoma*, also referred to as *juvenile adenocarcinoma of the pancreas*. Pancreatoblastoma is somewhat more common in boys than in girls and typically has slow growth with low malignant potential as well. Histologic examination demonstrates undifferentiated ductular and acinar areas with nodules of squamous epithelium, suggesting that these tumors arise from primordial pancreatic cells. Both papillary cystic neoplasm and pancreatoblastoma have more favorable prognoses than adenocarcinoma following surgical resection.

Endocrine Lesions of the Pancreas

Zollinger–Ellison Syndrome

Childhood tumors of the endocrine pancreas are exceedingly rare. The diagnosis and management of these tumors do not differ greatly from the adult population. The most common of these lesions include gastrinoma and insulinoma. The functional endocrine tumors of the pancreas are characterized by secreted peptide products such as glucagon, vasoactive intestinal peptide, somatostatin, and pancreatic polypeptide.

Similar to adults, children with Zollinger–Ellison syndrome clinically present with symptoms related to gastric hypersecretion. Peptic ulcer disease with or without gastrointestinal hemorrhage, abdominal

pain, and diarrhea are common presenting symptoms. The diagnosis is confirmed by finding elevated serum gastrin levels. The basal acid output typically is elevated as well. A paradoxical increase in serum gastrin levels is found following intravenous administration of secretin (secretin stimulation test).

Contemporary management of Zollinger–Ellison syndrome in children relies on control of gastric acid hypersecretion with the oral administration of a proton–pump inhibitor. Diagnostic imaging studies, including helical CT scanning and MRI, are useful in localization of a primary gastrinoma and evaluating for metastatic disease before exploration. Definitive treatment relies on complete excision of the primary gastrinoma, which typically is found in the right of the superior mesenteric vessels in the head of the pancreas or the duodenum. The growth and progression of gastrinoma appear to be less aggressive in children than in adults; however, total gastrectomy occasionally is required in a child to control intractable symptoms related to persistent hypergastrinemia or metastatic disease.²⁰⁰

About 25% of gastrinomas occur in the setting of MEN syndrome, reviewed elsewhere in this book. At least 90% of patients with MEN type I have hyperparathyroidism secondary to hyperplasia. In addition, 30% to 80% of patients have pancreatic islet cell tumors and 15% to 50% have pituitary tumors.

Hypoglycemia

There are diverse metabolic causes for hypoglycemia in infancy and childhood. These include endocrinopathies such as panhypopituitarism, hypothyroidism, adrenal insufficiency, and congenital adrenal hyperplasia (adrenogenital syndrome). Several inborn errors of metabolism interrupt normal glucose regulatory mechanisms. Systemic disease states, perinatal stress, and sepsis can predispose an otherwise normal infant to low blood glucose levels. Infants who remain unresponsive to glucose infusion typically have inappropriately high circulating insulin levels for a given blood glucose level. Hyperinsulinemia should be suspected in any infant or child younger than 1 year with persistent hypoglycemia. There are heterogeneous causes for hyperinsulinemic hypoglycemia, but the most common historical cause in infancy is nesidioblastosis, which is characterized by uncontrolled development of the pancreatic endocrine tissue that functions abnormally during infancy.^{201,202} Clinically, these cells secrete inappropriately high amounts of insulin, causing clinical hypoglycemia in infants. Two distinct histologic lesions appear to be responsible for congenital hyperinsulinism. Mutations in the beta cell K_{ATP} channel genes may lead to either focal, adenomatous hyperinsulinism or diffuse hyperinsulinism; both genotypes lead to phenotypic hypoglycemia if left untreated.

Infants with congenital hyperinsulinism usually become symptomatic from hypoglycemia within the first few hours or days of life. These infants commonly present with neurologic symptoms such as lethargy or generalized seizures and have corresponding fasting blood glucose levels below 40 mg/dL. The diagnosis of hyperinsulinemia is supported by the clinical features of Whipple triad that includes (a) neurologic changes with fasting or activity, (b) fasting blood glucose levels below 40 to 50 mg/dL, and (c) neurologic symptoms reversed by the administration of glucose. The diagnosis is made by demonstrating inappropriately high levels of circulating insulin for a given level of blood glucose. An insulin (IU/mL) to glucose (mg/dL) ratio that is greater than 0.5 in a fasting patient is consistent with hyperinsulinemic hypoglycemia. In infants and children, an absolute insulin level greater than 5 IU/mL in the presence of a blood glucose less than 40 mg/dL is diagnostic. Ketone body production is impaired in infants with congenital hyperinsulinism.

The initial management of a hypoglycemic infant with congenital hyperinsulinism is to provide adequate glucose concentrations to prevent permanent neurologic injury. Dextrose-containing intravenous solutions are titrated to maintain blood glucose levels greater than 40 mg/dL and may require a central venous catheter. The short-term administration of somatostatin analogues to increase blood glucose levels in hyperinsulinemic states has been demonstrated to be useful.²⁰³ Other pharmacologic agents used to reduce insulin levels and raise blood glucose concentration include diazoxide (15 mg/kg daily). The use of streptozocin to control hyperinsulinemia most often is reserved for adults with metastatic islet cell carcinoma and is not widely used in infants because of the potential side effects.

Following initial control of blood glucose and clinical confirmation of hyperinsulinemia, operative intervention should be considered a means of providing definitive control of hypoglycemia. Diagnostic imaging using CT scan imaging, MRI, or more recently,¹⁸ F-FDOPA PET scanning may be useful either to identify or to exclude a focal lesion.²⁰⁴ Localization of focal lesions is important in that this approach may lead to effective glucose control with selective partial pancreatectomy and allow for preservation of normal pancreatic tissue and function.^{205,206}

Operatively, the abdomen is explored thoroughly, and the entire pancreas must be visualized.

Preoperative localization data guided by intraoperative ultrasound and frozen section analysis may identify focal lesions amenable to partial resection. In the absence of a focal lesion, the infant is presumed to have diffuse islet cell hyperplasia. In this setting, the general operative strategy is total or near total pancreatectomy.²⁰⁷ Lesser procedures such as subtotal (80%) pancreatectomy do not effectively treat diffuse congenital hyperinsulinism and recurrent hypoglycemia places the infant at risk for hypoglycemic encephalopathy. Near-total pancreatectomy involves resection of the distal 95% of the gland with preservation of the spleen. The entire distal pancreas, including the uncinate process, is resected, leaving a small rim of pancreatic tissue adjacent to the duodenum (Fig. 103-58). Total pancreatectomy is usually reserved for persistent or recurrent hypoglycemia following lesser procedures. Near-total pancreatectomy controls hypoglycemia in 90% of infants with diffuse congenital hyperinsulinism. The remaining infants with persistent hypoglycemia may require further pancreatic resection. With extensive pancreatic resection, the typical postoperative course is a transient period of hyperglycemia with subsequent stabilization of blood glucose levels. Pancreatic exocrine function is ablated and oral replacement therapy is required. Despite clinical remission following resection, however, diabetes mellitus may occur as a long-term consequence in children treated either medically or surgically for diffuse congenital hyperinsulinism.²⁰⁸ Therefore, these infants need long-term metabolic follow-up for both pancreatic endocrine and exocrine function.

Figure 103-58. Illustration of the various degrees of pancreatic resection.

Chapter 104

Pediatric Genitourinary System

John M. Park and Julian Wan

Key Points

- 1 Embryonic kidneys develop from the intermediate mesoderm, with the definitive kidney forming as result of inductive interaction between ureteric bud and metanephric mesenchyme. Paramesonephric (müllerian) and mesonephric (wolffian) ducts contribute reproductive structures.
 - 2 Multicystic dysplastic kidney (MCDK) is the most common form of congenital cystic disease. It rarely causes any clinical problems and often involutes over time.
 - 3 Ureteropelvic junction obstruction (UPJO) is the most common form of hydronephrosis detected in utero.
 - 4 Ureteral duplication is a common anomaly. Upper pole ureter can be associated with either obstructing ureterocele or ectopic ureter, whereas lower pole ureter is more likely to be associated with vesicoureteral reflux.
 - 5 Vesicoureteral reflux (VUR) is an important problem to identify and manage in children who present with urinary tract infection (UTI). VUR can lead to recurrent parenchymal renal infections, resulting in renal scarring and other lifelong problems such as hypertension and pregnancy-related complications.
 - 6 Posterior urethral valve (PUV) is the most common congenital obstructive uropathy that leads to end-stage renal failure and renal replacement therapy. When severe, it can lead to oligohydramnios, renal failure, and pulmonary hypoplasia.
 - 7 Hypospadias is common, occurring in 1 of 200 live births. In most cases, they are mild, presenting with urethral opening near the distal shaft and glans. When associated with cryptorchidism, the differential diagnostic possibilities must include disorders of sex development (intersex).
 - 8 Undescended testicle occurs in 3% to 4% of full-term newborn males. If it remains ectopic beyond age 1, surgical orchidopexy should be performed prior to age 2 to 3 to preserve future fertility potential. When testicles are nonpalpable, laparoscopy is the gold standard to locate an intraabdominal testicle or confirm testicular absence.
 - 9 Prepubertal testicular tumors are benign unless associated with an elevated alpha-fetoprotein (AFP), in which case yolk sac tumor should be suspected. Testicular sparing enucleation is appropriate for mature teratomas.
 - 10 Patients with neurogenic bladder disorders (such as spina bifida) must be evaluated with urodynamic pressure–volume study to characterize its urine storage and emptying function. Managing bladder pressure and emptying with clean intermittent catheterization (CIC) is paramount to preserve renal health and improve quality of life.
-

1 FETAL DEVELOPMENT OF GENITOURINARY SYSTEM

Kidneys develop as paired intermediate mesodermal structures stretching craniocaudally along the length of the abdomen. The embryonic kidneys, in order of their appearance, are pronephros, mesonephros, and metanephros. *Pronephros* is nonfunctional and transitory in mammals. By the fifth week, it is replaced by *mesonephros*. The *mesonephros* is thought to provide a transient excretory function and also provides substrate for subsequent reproductive structures. The final step in renal development is *metanephros*, which becomes the true functional kidney. It develops in the sacral region as a result of inductive interaction between the ureteric buds (sprouting from the distal portion of mesonephric ducts) and the condensing blastema of metanephric mesenchyme. The nephron, which consists of glomerulus, proximal tubule, loop of Henle, and distal tubule, derives from the metanephric mesenchyme, while the collecting system, consisting of collecting ducts, calyces, pelvis, and ureter, is

formed from the ureteric bud. The kidneys ascend from their initial pelvic position to their final position in the upper retroperitoneum. At fifth week, the terminal portion of the endoderm-lined yolk sac dilates to become the cloaca. It is partitioned by the developing urorectal septum to form urogenital sinus anteriorly (future vesicourethral canal and vaginal vestibule) and anorectal canal posteriorly. During the fifth week, primordial germ cells migrate from the yolk sac to the posterior body wall near the mesonephros to form the genital ridges. In males, under the influence of SRY (the sex-determining region of the Y chromosome), primordial germ cells begin to differentiate into Sertoli cells, which then drive the formation of testis cords and Leydig cells (responsible for producing androgen). In females, the *paramesonephric ducts* (lying medially adjacent to the mesonephros; also known as the müllerian ducts) develop into reproductive structures, namely upper vagina, uterus, and fallopian tubes. In males, mesonephric ducts (known as the wolffian ducts) develop into vas deferens and epididymis under the influence of androgen. The presence of müllerian inhibiting substance (MIS) produced by Sertoli cells of a developing testicle causes müllerian ducts to regress in males. In females, in the absence of Sertoli and Leydig cells, mesonephric (wolffian) ducts regress and müllerian ducts continue to develop into female reproductive structures. Starting sixth week, under the influence of androgen and more importantly, dihydrotestosterone (converted intracellularly by the enzyme 5-alpha reductase), the genital tubercle elongates and the genital and urethral folds fuse in the midline to form scrotum, penis, and penile urethra. The formation of distal glandular urethra occurs by a combination of urethral fold fusion proximally and the ingrowth of ectodermal skin tag distally. Both developing testicles and ovaries move to the pelvic location by the third month. In males, with androgen-influenced regression of cranial suspensory ligament and swelling/contraction of gubernaculum, the testicles undergo inguino-scrotal descent during the third trimester.

ANOMALIES OF THE KIDNEY

Renal anomalies can be categorized into several recognized variants in position, number, and shape.¹ When the kidney does not move to the normal expected position, it is termed an *ectopic kidney*. A kidney that fails to ascend and remains near the bladder becomes a *pelvic kidney*, thought to occur in 1 of 3,000. It can travel too far and rise above the ipsilateral diaphragm to become an *intrathoracic kidney*. It can cross over to the other side and end up in a contralateral position as a *crossed ectopic kidney*. Crossed renal ectopia occurs with renal parenchymal fusion in 90%. Unlike the more commonly encountered ureteral duplication, crossed ectopic kidney's ureter crosses over the midline and drains into the bladder in the contralateral side. In 30% to 50%, ectopic kidneys can have varying degrees of hydronephrosis and vesicoureteral reflux (VUR). Most ectopic kidneys are asymptomatic and clinically insignificant, except in cases of associated ectopic ureter. The adrenal glands develop independently from the kidney, and it should be in normal position beneath the diaphragm, even if the ipsilateral kidney is ectopic. The possibility of an ectopic kidney must be entertained if a kidney is missing in the usual location during an exploratory laparotomy.

The embryonic metanephros can become fused at their caudal ends. The most common form of this anomaly is the *horseshoe kidney*, so named because the lower poles of the kidneys are linked either by a fibrous band or a section of functional tissue. It has an incidence of 0.2%. Horseshoe kidneys are notable for their low position in the body due to isthmus trapping by the inferior mesenteric artery. VUR and ureteropelvic junction obstruction (UPJO) have been found in up to 50% of patients with a horseshoe kidney.

In addition to anomalies of position and fusion, there can be an extra or *supernumerary kidney*. This very rare finding is usually discovered incidentally and occurs because there is separation of the metanephric blastema allowing a distinct kidney to develop. This should not be confused with a duplicated system where there are two collecting system draining a single kidney.

Failure of the ureteric bud to form or join the metanephric mesenchyme will result in *renal agenesis*. Bilateral renal agenesis is very rare and the infants with this condition are either stillborn or perish soon after birth due to respiratory failure. The characteristic Potter face and the presence of severe oligohydramnios are pathognomonic. When unilateral renal agenesis occurs, it is associated with a variety of other genitourinary findings; about 50% will still have a vestigial ureter, and about 30% will have VUR. Anorectal anomalies are also common. müllerian duct anomalies – such as uterine duplication or vaginal septum – occur in 25% to 50% of females with unilateral renal agenesis, and likewise, up to one-third of females with müllerian duct anomalies will have unilateral renal agenesis. It is important to note that true agenesis is relatively rare and should not be confused with a regressed

dysplastic kidney, which is a common fate of a *multicystic dysplastic kidney (MCDK)*.

2 Cystic Conditions of the Kidney

Renal cystic conditions are among the most common causes of pediatric abdominal masses, especially in infants.² It is important to accurately diagnose them due to their different prognosis and other associated conditions (Table 104-1).

MCDK is the most common form of nonheritable renal cystic condition.³ Prior to prenatal sonographic screening, it used to be the most common cause of an infantile palpable abdominal mass and was often confused with the UPJO. *MCDK* is a developmental anomaly resulting in multiple noncommunicating cysts of varying sizes and is without identifiable renal parenchyma. There is typically an associated atresia of the ureter. The classic ultrasound findings are: absence of a large central lucency (that could be confused with renal pelvis), variably sized noncommunicating cysts, and absence of renal parenchyma. *MCDK* is nonfunctional, and nuclear scintigraphy shows no activity. Majority of *MCDK* will involute and regress with time to the point that they may become undetectable on conventional ultrasound. For patients with a very large *MCDK*, they may not complete involution and a small residual clump of cysts may persist into adulthood. There is a high incidence (15% to 25%) of contralateral VUR. Several long-term registries have shown that patients with *MCDK* do well, and previous concerns of hypertension, infection, malignancy, and pain are thought to be very rare. Surgery is rarely necessary unless there is confusion about the diagnosis with a cystic Wilms tumor or failure to regress with worrisome changes on serial imaging. Rarely, it will cause any symptoms.

Table 104-1 Classification of Congenital Renal Cystic Diseases

Inheritable
Autosomal recessive (infantile) polycystic kidney disease (ARPKD)
Autosomal dominant (adult) polycystic kidney disease (ADPKD)
Juvenile nephronophthisis
Medullary cystic disease
Congenital nephrosis (familial nephrotic syndrome)
Familial hypoplastic glomerulocystic disease
Renal cystic syndromes (tuberous sclerosis, von Hippel–Lindau disease)
Noninheritable
Multicystic dysplastic kidney (MCDK)
Benign multilocular cyst (cystic nephroma)
Simple cysts
Medullary sponge kidney
Acquired renal cystic disease
Calyceal diverticulum

Autosomal recessive polycystic kidney disease (ARPKD) – also known as infantile polycystic kidney disease – results from mutations in the PKHD1 gene of the chromosomal locus 6p12.2. The classic presentation is a child born with bilateral large palpable kidneys that appear very bright on ultrasound. The hyperechogenic appearance is due to the multiple cystic surfaces reflecting the sonographic waves. Kidney function is uniformly poor, and oligohydramnios with pulmonary hypoplasia occurs in up to 50%. Among those who survive infancy, 30% progress to end-stage renal failure. Long-term survivors can also develop portal hypertension, esophageal varices, and hypersplenism due to concomitant periportal fibrosis. There is no specific therapy other than kidney transplantation.

Autosomal dominant polycystic kidney disease (ADPKD) – adult-onset type – primarily affects the kidneys but also can have significant effects on the pancreas, liver, brain, and blood vessels. The usual onset is postpubertal with most patients progressing to renal failure by the fourth to sixth decade of life, depending on the severity of penetrance. Two gene mutations are associated: PKD1 (85%) and PKD2 (15%) on chromosome 16. These genes encode membrane proteins that affect cilium and calcium signaling. Cysts are present in the pancreas and liver, as well as cerebral berry aneurysms in the circle of Willis. Autopsies of patients with ADPKD found that 22% have cerebral aneurysms, and about 10% of adult patients with ADPKD die of subarachnoid hemorrhage. Though primarily a condition of

adolescents and adults, pediatric care providers should be aware of ADPKD due to the nature of its inheritance. It affects 1 in every 400 to 1,000 people.

Acquired renal cystic disease of renal failure (ARCD) is a term that refers to the development of renal cysts in patients with end-stage renal failure. Regardless of the type of therapy (peritoneal or hemodialysis), cysts can develop in the kidneys. The longer the period of time of dialysis the more prevalent the cysts become. By 10 years of dialysis, 90% will have cysts. Transplantation and the restoration of normal renal function lead to cessation and regression of the cysts. The cysts are notable because they can bleed and develop infections. More worrisome is the development of renal cell carcinoma in about 0.2% of patients with ARCD. The condition occurs in equal frequency in adults and children.

There are other conditions that are associated with renal cysts. *Tuberous sclerosis* is an autosomal dominant condition characterized by mental retardation, epilepsy, sebaceous acne, and renal mass. The renal tumors are benign hamartomas (usually angiomyolipomas), but cysts are also common. *Von Hippel–Lindau syndrome* is an autosomal dominant condition with cerebellar hemangioblastoma, retinal angiomas, pheochromocytoma, renal cell carcinoma (30% to 40% of all VHL patients), and cysts of the pancreas and kidney.

Solitary Kidney

Patients with a solitary functional kidney in most cases can be expected to live a nearly normal life with few limitations.⁴ Solitary kidney can be due to surgical removal for disease, congenital malformation, trauma, regression of an MCDK, renal donation, or in rare cases, true agenesis. In general there are no limitations on sports or other activities. Participation in contact sports (such as football, rugby, and ice hockey) is allowed with the understanding that the participant use all of the needed protective gear and that the risk of injury leading to organ loss is very small but not zero. For example, in American tackle football, the risk of having cardiac arrest due to a blow to the chest, heat stroke during training, or suffering a catastrophic central nervous system injury is actually much higher than the risk of losing a kidney. For this reason the official position of the American Academy of Pediatrics is to allow participation in general. It is advisable that patients know their history and be able to identify the side of their functional kidney. It is also important to be aware that not every protective gear is subject to standardized testing and evaluation. Helmets used in American football, soccer shin guards, and eye protections are regulated, but most abdominal paddings are not. Therefore, although it would seem that protection should be helpful, use of such gear should not give a false sense of security.

3, 4 ANOMALIES OF THE URETER

Ureteropelvic Junction Obstruction (UPJO)

UPJO is the most common form of congenital ureteral obstruction and is also the most common cause of prenatally detected hydronephrosis.⁵ Multiple factors lead to poor transit of fluid across the obstructed UPJ. There can be an intrinsic adynamic portion wherein the muscles lining the UPJ are aberrant. The muscle fibers are deficient and replaced with collagen. The net effect is to alter the normal propagation of the peristaltic waves. In addition to these intrinsic issues, there can be extrinsic factors such as fibrous bands or aberrant lower-pole crossing vessels trapping the ureter at the UPJ.

The classic symptoms of UPJO are flank/abdominal pain, hematuria, and infection. Inexplicable vomiting may be mistakenly termed idiopathic. Today many UPJO cases are diagnosed antenatally due to abnormal prenatal ultrasound (Figs. 104-1 and 104-2). Ultrasound findings of dilated renal pelvis and calyces without ureteral dilation are indicative of UPJO, but it cannot definitely establish the presence of a true surgical obstruction. Functional study, such as diuretic nuclear renography, is commonly required to assess both relative renal function and severity of obstruction. Magnetic resonance urography is a newer modality, which is increasingly utilized because it avoids ionizing radiation and yields excellent functional and anatomic details. Not all antenatally discovered UPJO need immediate surgery, and many could be safely observed with spontaneous resolution in some, especially those with a preserved relative renal function.

Figure 104-1. Ultrasound demonstrating dilated renal pelvis and calyces caused by ureteropelvic junction obstruction.

UPJO repair can be done effectively using an open or laparoscopic approach, with possible aid of a surgical robot. The principle is to excise the narrowed, dysplastic portion and reconnect the ureter and renal pelvis back together to create a dependent drainage (Fig. 104-3). This dismembered pyeloplasty can be done with a better than 95% success rate. Other approaches using pelvic flap are applied selectively based on the anatomy.

Ureteral Duplication

Ureteral duplication is a common anomaly of the urinary tract. The incomplete duplication has two ureters exiting the kidney, but they join prior to entering the bladder, so there is only one ureteral orifice in the bladder. A complete duplication has two ureters that enter the bladder separately, resulting in two orifices. These occur in about 1 in every 150 to 500 individuals. In a complete duplication, the upper pole ureter ends up with a more inferior and medial orifice closer to the bladder neck while the lower pole ureter has a superior and lateral orifice (Weigert–Meyer rule). The more lateral position of the lower pole ureter can result in potentially shorter submucosal tunnel, making it more prone to VUR. The more medial upper pole ureter, on the other hand, can enter ectopically into the bladder neck and proximal urethra, resulting in obstruction. In females, the ectopic upper pole ureter can drain to the vestigial Gartner duct (wolffian duct remnant) and thereby open up onto the anterior lateral vaginal wall, resulting in continuous incontinence. In males, the ectopic upper-pole ureter can insert into reproductive structures such as vas deferens and seminal vesicle, resulting in obstruction or recurrent epididymitis. Most patients with partial or complete duplication are otherwise healthy.

Figure 104-2. Prenatal sonography showing dilated left renal pelvis with thin parenchyma caused by ureteropelvic junction obstruction.

Figure 104-3. Dismembered pyeloplasty where the obstructive segment has been excised and the anastomosis is performed between the pelvic opening and spatulated ureter, creating a dependent drainage.

Ectopic Ureter

Ectopic ureter usually drains more caudal and inferior to the normal trigone. It is commonly associated with a complete duplication. In males, they can exit into the prostatic urethra, bladder neck, and epididymis (rare). In females, they can drain into the bladder neck, urethra, and vagina. For girls, an ectopic ureter that drains outside of the bladder is the classic cause of persistent day and night wetting despite otherwise excellent toilet habits. This can be a vexing condition for many patients and families, but once properly diagnosed, it offers one of the most successful surgical solutions for incontinence ([Fig. 104-4](#)). Treatment is usually upper pole partial nephrectomy or reimplant of the upper pole ectopic ureter into the bladder.

Ureterocele

Ureterocele develops as the result of a narrowed opening of the ureteral orifice.⁶ The narrow opening results in submucosal and ureteral dilation that can extend all the way up to the kidney. The dilation varies in severity. It can be mild, contained wholly within the bladder wall and appear like a pearl onion ([Fig. 104-5](#)). Or it can be massive and create a cavernous space under the trigone, extending beyond the bladder neck and into the urethra ([Fig. 104-6](#)). Ureteroceles are typically associated with upper pole ureter of a complete duplication. Single-system ureteroceles do occur but are rare. Similar to UPJO, they are often found as part of an antenatal hydronephrosis evaluation. Other common presentation is symptomatic urinary tract infection (UTI) or prolapse. Infected ureterocele can cause severe sepsis and requires an emergent decompression of the ureterocele using an endoscopic transurethral puncture. Options for longer term, more definitive treatment approaches are designed depending on the salvageable function of the upper moiety. If the upper pole is functional, it is usually preserved, and the surgical approach is aimed at eliminating the distal ureteral obstruction at the ureterocele. The dilated ureter is tapered and reimplanted into the bladder after excising the ureterocele, either separately or en bloc with the normal lower-pole ureter in a common sheath. Alternatively, the upper pole ureter can be connected to the lower-pole pelvis (ureteropyelostomy) near the kidney. If the upper pole is nonfunctional, a partial nephrectomy is preferred. Advances in minimally invasive surgery make laparoscopic and robotic techniques practical in even small children.

Figure 104-4. Ectopic ureter opening outside the bladder and urethra causing continuous incontinence. Catheter is inserted into the left upper pole ectopic ureter.

Figure 104-5. Intravenous urogram demonstrating ureterocele that has an appearance of “Pearl onion.”

Figure 104-6. Bulging right ureterocele belonging to the upper pole. Bladder has been opened. Catheters are inserted into the right lower pole ureter and left ureter.

Megaureter

A persistently dilated ureter from the kidney all the way to the ureterovesical junction (UVJ) is referred to as megaureter.⁷ They are classified by description and causation. They can be refluxing, obstructing, refluxing/obstructing, and nonobstructing/nonrefluxing. When they are due to an intrinsic abnormality of the distal ureter (such as fibrosis of the UVJ), it is called primary megaureter. When it is caused by another condition of the bladder (such as a neurogenic bladder or bladder outlet obstruction), it is called a secondary megaureter. Primary megaureters, like UPJO and ureterocele, are often diagnosed prenatally. Majority of moderate megaureters – especially those detected in utero – improve with observation. If they require treatment because of pain, UTI, or poor renal function, they can be temporarily drained with a stent, nephrostomy, or cutaneous ureterostomy. Long-term solution requires a ureteral reimplantation with tapering of the wide ureter.

5 Vesicoureteral Reflux

The ureter transports urine from the pelvis to the bladder with active antegrade peristalsis. Once in the bladder, the urine is stored until it is emptied without sending the urine back toward the kidney. This whole process is independent of gravity. When the bladder urine moves in a retrograde manner toward the kidney, it is termed as VUR ([Fig. 104-7](#)).⁸ It is an abnormality that can occur primarily due to a congenital deficiency in the UVJ submucosal tunnel or secondarily to high bladder pressures such as in patients with neurogenic bladder or posterior urethral valves (PUVs). The incidence of VUR in general population is estimated to be around 1%. The incidence is much higher in children who present with UTI and hydronephrosis. Among children age 4 years or less who present with a first-time UTI, the VUR incidence can be as high as 40%. VUR is found in 25% to 30% of children with antenatal hydronephrosis. The primary form of VUR occurs because the length of the intramural tunnel – so-called flap valve (like stepping on a straw on the ground) – is insufficient to seal the ureter during bladder filling and emptying. The secondary form usually occurs because of high storage pressure that overwhelms an otherwise normal intramuscular tunnel. Reflux is of clinical significance because it interferes with effective emptying of urine and helps bacteria ascend to the kidneys more easily, thereby transforming cystitis into potentially damaging renal parenchymal infection (pyelonephritis). Pyelonephritis in turn increases the risk of long-term kidney damage by creating parenchymal scar. Infants and children are more prone to scarring than adults. Renal scarring and damage early in life can increase the risk of hypertension and pregnancy-related complications in females.

Figure 104-7. Vesicoureteral reflux to the left lower pole ureter.

VUR severity is described using the International Reflux Study scale. Grading is important for several reasons. Most VUR patients (80%) have grades I or II with an excellent chance of spontaneous resolution (75% to 90%) over time. The higher grades (III to V) are less likely to improve with time and more often require surgery. The diagnosis of VUR depends on the demonstration of reflux on an imaging study. Voiding cystourethrogram (VCUG) is the preferred imaging modality. It offers excellent anatomical detail of the entire lower urinary tract (bladder and urethra) and reproducible grading. In males, it provides important details regarding urethra such as possible valves. The presence of other anomalies such as periureteral diverticulum can affect the clinical decision-making. Alternatively one can use nuclear cystogram (NUC) that offers less anatomical detail and a different grading system (grades 1 to 3) but is offset by the advantage of less radioactive exposure and the ability to continuously monitor reflux throughout filling and emptying. Ultrasound of the kidneys and bladder, while helpful in assessing renal size and appearance, cannot diagnose reflux. The detection of kidney scarring is usually confirmed with nuclear renal scintigraphy using DMSA ([Fig. 104-8](#)).

Figure 104-8. DMSA renal scintigraphy demonstrating renal parenchymal defect associated with pyelonephritis. **A:** Cortical defects seen in the right kidney during the acute phase of pyelonephritis. **B:** The same kidney 6 months later showing a persistent cortical scar involving the upper pole.

The management of children with VUR depends on their presentation and other clinical factors (Fig. 104-9). The vast majority of patients have low-grade VUR and are expected to resolve spontaneously with time. They can be managed with low-dose antibiotic prophylaxis with intermittent testing every 1 to 2 years. The most recent multi-institution randomized clinical trial suggested that antibiotic prophylaxis is beneficial in children with dilating, high-grade reflux (grade III or higher). If they cannot remain infection free and sustain breakthrough infections, surgery may be necessary to prevent recurrent renal parenchymal infection. For most patients, spontaneous resolution occurs after 4 to 5 years and those who fail to resolve may also need surgery. There are two major surgical options. There is the less invasive endoscopic approach. Using cystoscope, a small bleb of a bulking material is injected into the floor of the ureteral orifice. This creates a submucosal mound that turns the usual round oval opening into an upside-down crescent. Currently, FDA-approved dextranomer/hyaluronic acid copolymer (Deflux®) is available for this approach. The efficacy of Deflux® injection is good but not spectacular. About 70% to 75% of VUR can be corrected with this approach. Lower the grade, the more likely that injection will succeed. The long-term durability also remains unknown. The more time-tested surgery for correcting VUR is ureteral reimplantation (ureteroneocystostomy), where the ureter is revised or repositioned to create a more effective ureterovesical flap-valve mechanism by restoring the submucosal tunnel. The affected ureter is detached and mobilized. A new submucosal tunnel of sufficient length (more than 4 to 5 times the width of the ureter) is created, and the ureter is placed into it. It is critical that the muscle underneath the tunnel is firm and secure to allow the collapse of the reimplanted ureter with bladder filling and emptying. The ureter may require tapering (in megaureter or obstructed upper pole of duplication anomaly), so it can meet the needed width-to-length ratio of the tunnel. An extravesical approach is called detrusorraphy, where the muscle flaps are freed from the underlying bladder mucosa and wrapped behind the ureter at the UVJ to create a more effective flap-valve mechanism. The success rate of open surgery for VUR is very high (96% or more for grades III or less).

Traditionally, all children who present with a culture-proven UTI were recommended to undergo evaluation for VUR using ultrasound and VCUG. More recently this paradigm has been called into question because of the observation that some children seem to tolerate VUR better than others without long-term clinical problems, especially those with low-grade VUR. A modified evaluation approach

using the initial ultrasound has been suggested. Because the key concern with VUR is the prevention of kidney damage and its consequences (hypertension, scarring, and loss of renal function), some argued that because most VUR are of low grade and most cases of low-grade VUR resolve spontaneously, it may be reasonable to defer VCUG for only those patients who have recurrent UTIs or whose ultrasound is abnormal. This led to a major shift in the recommendations from the American Academy of Pediatrics (AAP) in 2011. Others have argued that determining the presence of renal scarring should be the dominant factor and advocated an initial nuclear DMSA renal scintigraphy rather than ultrasound. Recently a double-blind controlled randomized clinical trial looked into the benefits of antibiotic prophylaxis. The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) study that completed in 2014 studied 600 children with proven VUR.⁹ Half received antibiotic prophylaxis and half received a placebo. Prophylaxis reduced the risk of recurrent UTI by 50%, especially in those with dilating, high-grade reflux (III to V). The occurrence of new renal scarring however did not differ significantly between the two groups.

Figure 104-9. International reflux grading system. Majority of reflux are grades I or II, with high likelihood of spontaneous resolution, whereas higher grades (III to V) with dilating ureters are at a greater risk of UTI, renal injury, and nonresolution, often requiring surgery.

Women with a history of VUR may be at increased risk later in life for UTI during pregnancy regardless of whether the VUR was corrected or not. Renal scarring rather than the presence of active VUR itself appeared to be a key risk factor for pregnancy-related morbidity. In general, for girls with VUR, the families should be aware that when they become adults of child-bearing age, they need to know their medical histories, so that appropriate perinatal care and monitoring is instituted.

BLADDER ANOMALIES

Urachal Abnormality

During fetal development, urachus is the cephalad attachment of the cloaca to the allantois. As the bladder and urethral sphincter develop, it becomes atretic. It remains only as a fibrous cord from the dome of the bladder to the umbilicus. Occasionally the urachus remains patent either completely or partially. When completely open (patent urachus), urine can be found exiting the umbilicus. In other cases, there can be a deep sinus or entrapped cyst. These can be areas that can be infected due to poor drainage and present with fever, nausea, and umbilical drainage. Detection is usually made by clinical suspicion, along with abdominal ultrasound or other imaging. Because the epithelial lining of the urachus is that of the bladder and not of the skin, rarely tumors can occur. Mucinous adenocarcinoma is thought to arise from the urachal remnant in middle-aged or elderly patients. For this reason, when detected, even when asymptomatic, some have advocated prophylactic removal.

Exstrophy–Epispadias Complex

During development if the cloacal membrane fails to breakdown at the appropriate time, medial migration of the mesenchyme to form the anterior abdominal wall is affected. The bladder can end up

as an exposed urothelial plate (*bladder exstrophy*) ([Figure 104-10](#)).¹⁰ The urethra may be incompletely formed dorsally (*epispadias*). The whole lower abdomen can be exposed with the hindgut or colon being unformed with the bladder split into two halves (*cloacal exstrophy*). Pelvic bone is also abnormally developed, and there is a diastasis of pubic symphysis.

The least severe manifestation is epispadias. In males, it is a defect with a dorsally placed urethral meatus and urethra, along with dorsal penile curvature. Visually it looks like a reverse, dorsal form of hypospadias. When the meatus is very proximal, the bladder neck and continence can be affected. In females, epispadias typically present with bifid clitoris ([Fig. 104-11](#)). It is more commonly associated with bladder exstrophy, but can occur as an isolated defect. Recognition and protection of the bladder plate against contact irritation is important. If possible, primary closure of the exposed bladder plate, pelvic placement and abdominal closure should be done during infancy. Most studies have suggested that a concomitant pelvic osteotomy is beneficial for successful initial closure as well as the subsequent bladder function. Repair can be staged with closure of the bladder first, followed by later bladder neck reconstruction and epispadias repair. Alternatively a complete primary repair could be accomplished with simultaneous closure of the bladder plate and reconstruction of the epispadias and genitalia. Bladder exstrophy is associated with other anomalies including inguinal hernia and VUR.

Figure 104-10. Male bladder exstrophy with associated epispadias.

The most severe form of exstrophy disease is the cloacal exstrophy. The hindgut (colon, rectum, and anus) is absent or rudimentary. The bladder plate is split into two parts on either side of the exposed cecum and hindgut remnant along with omphalocele. Initial management involves repairing the omphalocele, creating a colostomy, and dissecting the bladder plates free and reconstruct to form a reservoir. In cloacal exstrophy, there is also spina bifida with an abnormal sacrum and lower spine.

Figure 104-11. Female epispadias with its classic bifid clitoris.

6 ANOMALIES OF THE URETHRA

Posterior Urethral Valves

One of the most important obstructive uropathy in males is PUV.¹¹ This condition occurs when a thin membrane of tissue forms below the verumontanum and above the external sphincter, causing a blockage of antegrade flow of urine from the bladder. This results in high voiding pressures proximally leading prostatic urethra dilation, bladder wall hypertrophy (similar to cardiac hypertrophy due to hypertension or aortic stenosis) and VUR. Most patients today are diagnosed because of antenatal hydronephrosis. Classic prenatal sonographic findings are bilateral hydroureteronephrosis, large bladder, and enlarged prostatic urethra (so-called “Keyhole” urethra). The poor bladder emptying throughout fetal development can result in dysplastic poorly functional kidneys and low urine production. Oligohydramnios (as result of low urine output) can lead to poor pulmonary development and concomitant respiratory issues. Initial postnatal treatment is to achieve immediate urethral drainage (usually with a small diameter feeding tube) and obtain VCUG when stable to establish diagnosis (Fig. 104-12). Most patients undergo endoscopic resection of the valves. If the patient is too small to accommodate an infant resectoscope (8.5 Fr), a temporary diverting vesicostomy may be appropriate. Supravesical diversion such as ureterostomy is rarely needed.

There are several long-term urologic concerns for boys with PUVs. PUV remains the leading urologic cause resulting in renal insufficiency and transplantation. The initial nadir creatinine with complete bladder drainage is prognostic. Patients with nadir values at or below 0.8 mg/dL seem to be able to transition into adulthood without needing dialysis or transplantation. The early fibrosis and hypertrophy of the bladder makes valve boys more prone to develop poorly compliant bladders. These bladders have higher than normal storage pressures and over time can lead to the development of stones, incontinence, urinary retention, and worsening renal functions. When recognized early, appropriate therapy using clean intermittent catheterization (CIC) along with antimuscarinic agents (such as oxybutynin) to relax the bladder muscle can help manage these so-called “Valve bladders.”

Figure 104-12. Voiding cystourethrogram of a newborn with posterior urethral valve. Bladder wall is thickened from chronic in utero obstruction. Bilateral severe vesicoureteral reflux is also shown.

7 Hypospadias

Hypospadias occurs when the ventral genital folds do not fuse completely.¹² The majority of cases do not have a known cause. There are a few important associations. When hypospadias is found concomitantly with an undescended or missing testicle, the probability of a disorder of sex development (DSD) is high enough to warrant a formal work-up. Recently there has been a growing interest in the role of endocrine disruptors. These are a class of agents that are not steroids but may act on steroid receptors. They include agents such as bisphenol A, polychlorinated biphenyls, phytoestrogens, and other common commercial and industrial compounds. They can fully or partially mimic natural hormones by binding with androgen receptor, thus altering the effect of endogenous sex hormones.

There are three anatomic elements in hypospadias: the urethral opening is low, the ventral shaft is less well developed and classically curves toward the scrotum (called chordee), and the foreskin is incomplete, being usually absent ventrally and heaped-up dorsally in a hood-like formation (Fig. 104-13). Most cases (80%) are distal with the meatus being near the tip of the penis or at the neck (corona). Not all cases require surgery. Milder forms which do not interfere with normal voiding and whose erections are sufficient for future sexual intercourse may not need correcting, other than cosmetic concerns.

Surgical repair aims to create a functional penis that allows normal stand-up voiding and straight erections with good cosmesis.¹³ The urethral meatus is advanced to normal position on the glans. Any significant chordee is corrected as well. There are a variety of techniques that can be used depending on the severity of the hypospadias. These can be done as a single-stage or in multiple stages for the severe type (Fig. 104-14). The prepuce is a rich source of possible free graft and vascular flaps. When suspected of having hypospadias, a newborn should not be circumcised until a pediatric urologist has made an assessment. In some cases, particularly those who had undergone many failed prior attempts at repair, there may not be sufficient local tissue. Grafts taken from the buccal mucosa of the inner lip or cheek can be used effectively as a urethral substitute. Complications include urethrocutaneous fistula, strictures, meatal stenosis, recurrent chordee, and surface skin irregularities. Long-term follow-up is needed in these patients because complications can occur years after the total repair.

Figure 104-13. Mild hypospadias with urethral meatus located near the neck (corona), along with dorsal hood foreskin.

Figure 104-14. Severe hypospadias with perineal urethral opening along with severe ventral shaft curvature (chordee).

Disorders of Sex Development (DSD)

When the genitalia do not develop in a manner that is clearly male or female in appearance, the term disorder of sex development (DSD) is applied.¹⁴ It supersedes older terms such as intersex and hermaphroditism. This is an evolving field and covers a spectrum of disorders, some of which can pose a significant physiologic and mental health risk. There are daunting concerns over gender assignment and genital reconstruction. For these reasons, many centers have developed specific DSD teams that aim to provide a comprehensive, integrated care. Comprised of experts from urology, general surgery, gynecology, genetics, endocrinology, social work, psychology, and ethics, they develop an organized, systematic approach to evaluating and treating the patients with DSD while keeping the family continuously educated as the child grows. Many patients, especially those who were diagnosed late or who had poor earlier experiences, can have great concerns about secrecy and confidentiality. Much of what is known of the long-term outcome remains anecdotal and incomplete, lacking robust clinical outcome data to guide management during infancy.

All patients with suspected DSD require a thorough physical examination, especially of the genitalia and perineum, along with a detailed pregnancy, family, and social history. Evaluations, including electrolytes, steroid levels and precursors, gonadotropins, and karyotype, are typically assessed with further specialized tests ordered as necessary. Imaging includes renal/pelvic ultrasound and genitogram. Magnetic resonance imaging, cystoscopy, laparoscopy, and gonadal biopsies may also be necessary. Gender assignment options are reviewed with the family after all information concerning gonads, chromosome, physiology, fertility potential, and anatomy has been gathered and discussed.

Anomalies of the Penis and Prepuce

As a newborn, most infant boys have a natural physiologic phimosis. It is inappropriate and unnecessary to retract the foreskin in most boys until they are between ages 5 and 7 years. No special care of the uncircumcised phallus is needed. Spontaneous separation due to the accumulation of shed skin cells and secreted oil (forming smegma) and normal erections that occur even in small children naturally lift the prepuce away from the glans. No forceful retraction should ever be done during early childhood, since it can be very painful, traumatic, and can result in foreskin tear that will heal as a solid scar.

The indications for neonatal circumcision, arguably the single most common procedure performed worldwide, remains controversial.¹⁵ The clear-cut medical indications are not in dispute – phimosis, paraphimosis, and balanitis. True phimosis is the inability to retract the foreskin when the child is of an age when it should have occurred naturally. In milder cases, treatment with topical steroid ointment of the phimotic ring (such as betamethasone) can sometime loosen up the skin sufficiently that the foreskin stretches and can be retracted in up to 50%, thus avoiding circumcision. In more severe cases, circumcision is usually the most straightforward solution, but for families and patients who do not want to be circumcised a dorsal slit or partial circumcision can be performed. In paraphimosis, the foreskin is pulled back but cannot be repositioned, causing a vascular constriction in the corona. This is a true emergency because over time the prolonged retraction will cut off lymphatic and blood flow causing glandular necrosis. Emergency reduction is needed typically under general anesthesia followed by circumcision or dorsal slit at a later date. Finally for patients who have recurrent bouts of infection due to entrapment of bacteria under the foreskin (balanoposthitis), circumcision may be medically advisable. Circumcision is sometimes advised for boys who have recurrent urinary tract infections, PUVs, solitary kidney, or VUR to reduce future UTI risks.

Controversy exists for routine neonatal circumcision. This is typically performed as a religious rite, social or family custom, or concerns about future hygiene. Religious circumcisions are performed as part of a religious rite for many creeds and sects with the Jewish and Islamic faiths being two of the best known. In some cultures circumcision is done not because of a religious reason but for a social one – to be like other older male family members with circumcision. Finally there are some who have circumcision done because of a concern for future hygiene. After circumcision the covering of the glans changes from a columnar moist epithelium to a squamous dry and tougher coating. This change and the exposure of the glans were long theorized to help increase resistance to infection to sexually transmitted diseases (STD) and UTI. The data from the three large-scale randomized African studies on young men who underwent circumcision to assess its effect on STD transmission (notably HIV) demonstrated a statistically significant difference. However, clinically this effect may have limited utility because it does not prevent or cure any infection – it just proved that the tougher epithelium and a dry environment may lower infection-carrier risk. Another indication that is sometimes brought up is the risk of penile cancer. Penile cancer most commonly occurs in the prepuce, thus elective early removal is

theorized to help prevent later cases. However, the small benefit of reducing a relatively rare condition while subjecting many children to the risk of circumcision limits this argument. Meatal stenosis occurs in 5% to 7% of circumcised boys. This occurs when the meatal lips of the urethra rub or chafe against the diaper or underwear. Irritated by the urine, the raw areas heal to form a thin webbing of skin across the opening. The classic presentation is upward deflection of stream. It is also a common cause of dysuria (burning with urination) and terminal hematuria. Treatment is by splitting the web of skin (meatotomy).

8 ANOMALIES OF THE TESTICLE AND SCROTUM

Undescended or Cryptorchid Testicle

Embryologically, testicle forms just beneath the kidneys.¹⁶ During the 12th to 18th weeks of gestation, the testicles migrate down to a pelvic position just inside the internal inguinal ring. During the third trimester, the testicle travels through the canal, exits the external inguinal ring and enters the scrotum, driven by the swelling and contraction of gubernaculum under the influence of androgen. A scrotal position is advantageous for several reasons. Descended testicles are exposed to a lower temperature environment, and this is necessary for achieving full sperm development and fertility. Undescended testicles are also at increased risk for germ cell malignancy. A scrotal position makes self-examination after puberty easier, thus facilitating an early detection. Finally, undescended testicles that are positioned near the pubic bone can be more vulnerable to injury.

Physical examination plays a key part in the diagnosis of an undescended testicle. When boys are anxious or nervous, their inguinal cremasteric muscles tense up and can draw the testicle upward into the groin. This condition is termed retractile testicles. In most cases, the retractile testicle settles in the scrotal position by the time the child is ready to start elementary school. In some, retractile testicles can ascend to the inguinal region as the boys grow older, requiring a surgical intervention. This is referred as ascending testicle, and may occur up to 5% of boys who are followed for retractile testicles.

About 3% to 4% of normal full-term boys may have an undescended testicle at birth. The incidence is higher in premature infants. By age 1 year corrected for prematurity, this number drops down to around 1%. This figure remains stable through puberty. For this reason, one must allow (typically during the first 6 months of life) to see if the testicle will descend spontaneously, but if the testicle has not dropped by 1 year of life, waiting longer will not improve the situation, and surgical orchidopexy should be considered. Furthermore, leaving a testicle in an ectopic position beyond age 2 to 3 is thought to adversely affect future sperm cell (Ad spermatogonia) development. An undescended testicle could be inside the abdomen, having never engaged the internal inguinal ring. It could be inside the inguinal canal (canalicular) or through the external ring but not in the scrotum (superficial pouch). It can be truly ectopic, such as perineal and femoral. Finally, the testicle could be aberrant, dysmorphic, atrophic, or nonexistent. These are usually testicles, which suffered some form of perinatal vascular compromise that was not recognized prior to birth. The testicle seems to “vanish” over the first year of life (thus called vanishing testicle syndrome).

For palpable undescended testicles, the approach is usually through an inguinal incision. The testicle is mobilized by detaching gubernaculum, cremasteric muscle, and internal spermatic sheath around the cord structures, and a tunnel is created from the inguinal incision to the scrotum. There is usually an associated patent processus (up to 80% in infants), and this is separated from the cord and high ligated at the internal ring. For nonpalpable testicles, the most effective initial approach is laparoscopy. The key is to find the spermatic vessels. If spermatic vessels pass into the internal ring then the laparoscope is removed and a groin exploration is done. This may lead to a small undescended testicle, which may have been difficult to palpate in the inguinal fat. In other situations, there is an atrophic nubbin (typically within the scrotal sac) due to a probable perinatal torsion and vascular compromise. If the testicle is seen within the abdominal cavity and well away from the internal ring, the only viable surgical option may be a Fowler–Stephens orchidopexy (done as either single or two stage), where the gonadal vessel is divided and the testicle is brought down with a vassal collateral circulation (Figs. 104-15 and 104-16). In a staged orchidopexy, the dominant gonadal vessel is gently clipped laparoscopically, allowing the testicle to develop a dependence on the collateral circulation. At a second procedure 6 months or later, the gonadal vessel is divided, and the testicle is carefully brought down (either open or laparoscopically) with the vasal vessels. Laparoscopy has been shown to be the most effective in determining the absence of viable testicle (vanishing testicle syndrome). The pathognomonic finding is

blind ending gonadal vessels. If a blind-ending vas is seen but not the vessels, one must continue to explore for hidden testicular tissue since there is an unusual phenomenon of testicular–epididymal dysjunction, where the testicle is disconnected from the wolffian structures (epididymis and vas). One may have to look very far to locate the vessels, even going up behind the colon and near the lower pole of the kidney. Leaving a testicular tissue trapped within the abdominal cavity will increase the risk of germ cell malignancy. There are currently no reliable imaging studies that can obviate the need for surgical exploration, and diagnostic laparoscopy remains the gold standard. Ultrasound is not recommended. Although it is noninvasive, it suffers from the negative test result prediction concern. Most importantly, the surgical decision and planning are not altered by ultrasound findings. For bilateral nonpalpable testicles, biochemical markers – such as HCG stimulation test or serum MIS level – may be useful to determine the presence or absence of functional testicular tissue.

Figure 104-15. Intraabdominal testicle is gently clipped to force its dependence on the vassal collateral circulation (first-stage Fowler–Stephens orchidopexy).

Figure 104-16. During the second-stage orchidopexy, the testicle is dissected while being attached to the vassal collateral circulation.

Figure 104-17. Left intravaginal testicular torsion. The nontorsed contralateral testicle is also explored and secured to prevent future torsion.

Torsion of Testicle and Appendages

Torsion of the testicle is the leading nontraumatic cause of loss of the testicle in boys (Fig. 104-17).¹⁷ It is an emergent condition that occurs as result of the spermatic cord twisting. This results in occlusion of the lymphatic vessels, veins and arteries leading to ischemia, necrosis, and atrophy. If there is complete occlusion of blood flow, the testicle may be salvageable up to 6 hours after onset. After 6 hours the odds of salvage diminish exponentially. Most torsion occurs in older boys and adolescents – although it can occur at any age – with the torsion occurring inside the tunica vaginalis (intravaginal torsion). A horizontal lie (known as the bell-clapper deformity) caused by poor posterior fixation is believed to predispose toward torsion. Torsion can also occur among neonates, but this occurs due to poor gubernacular fixation and twisting of the cord outside the tunica vaginalis (extravaginal torsion). Neonatal torsion classically is associated with a prolonged labor. The testicle is very firm, and there can be a dark ecchymotic look about the scrotum. Successful salvage is very rare in perinatal torsion, and exploration is controversial due to potential anesthesia concerns. Because of the very low salvage rate, some do not advocate an emergent exploration, while others point out that if it is anesthetically safe, exploration is important because it establishes definitively not only the state of the suspected torsed testicle but allows fixation of the contralateral testicle. Metachronous torsion can occur and is difficult to monitor clinically. Exploration and preemptive fixation can prevent loss of the contralateral testicle.

The presentation is a sudden onset acute unilateral scrotal pain. The pain can be intense and lead to nausea and vomiting. With time, there will be increasing swelling and discoloration. The signs and symptoms will evolve over time. Initially there can be little swelling or redness. Later when the nerve endings have died out, the testicle and scrotum may still be swollen and ecchymotic but less painful. Various clinical clues may help guide physical examination. These include a noticeably shortened spermatic cord, absence of a cremasteric reflex, and lack of relief of discomfort with elevation, but these are often of limited practical use when faced with an anxious patient with a tender scrotum. If one has a strong clinical suspicion based on presentation, and there are no other medical or anesthetic reasons not to go to surgery, emergent exploration – without any further imaging – is appropriate. Doppler ultrasound – now readily available in most modern emergency departments – can be useful but should not delay exploration. Ultrasound can help identify other cases of acute scrotum such as torsed appendix testis, epididymitis, hernia/hydrocele, and idiopathic scrotal edema. Exploration is done through a transverse scrotal incision. If the testicle is necrotic, it should be removed to alleviate pain, and the contralateral testicle explored and sutured inside the scrotum in 3 to 4 quadrants to prevent future torsion. If a safe surgery is not an option, one may attempt a manual detorsion with a cord block. Untwisting as if one were opening a book (inside out) is the most commonly recommend technique, but it is by no means certain. Scheduling a prompt exploration is recommended even if there is relief with manual detorsion.

When the müllerian ducts atrophy in males, they can leave a remnant as a testicular appendage on the head of the testis. These can twist and mimic a full torsion. In pale-skinned patients, the torsed appendage during early presentation can resemble a painful small blue dot that is seen through the stretched skin. Because the appendage is vestigial and functionally useless, its torsion is managed with

pain relief, anti-inflammatories and exertion restrictions.

9 Prepubertal Testicular Tumors

There is a separate chapter that discusses common childhood tumors.¹⁸ For this chapter, we will limit our discussion to prepubertal testicular tumors. Most testicular tumors are nonseminomatous germ cell tumors. They usually present as a distinct palpable painless mass in the scrotum. They can have a reactive hydrocele, and it is important to palpate the entire testicle before assuming that the hydrocele is harmless. The primary imaging study is a scrotal ultrasound and biomarkers. The two most useful biomarkers are the alpha-fetoprotein (AFP) and beta-HCG. The most common types of prepubertal tumors are teratoma and yolk sac. Teratoma is benign in prepubertal age group. Histologically they contain all three germ layers (ectoderm, mesoderm, and endoderm). Due to the benign nature, testis sparing approach is warranted. An enucleation of the mass through a tunica albuginea incision is performed if the frozen section confirms the diagnosis (Figs. 104-18 and 104-19). Yolk-sac tumors are the most common malignant prepubertal tumor. Most present early as stage 1 (limited to the testicle and completely resected), and the AFP level will be elevated in the vast majority of cases. After radical inguinal orchiectomy, most are observed with serial imaging and tumor markers, provided that other staging work up is negative, with retroperitoneal lymph node dissection and systemic adjuvant chemotherapy being reserved for those with advanced disease (persistent retroperitoneal lymph adenopathy or increased serum markers). Seminomas and mixed germ cell tumors are extremely rare in prepubertal children, and their management should be as in adults. There are gonadal stromal tumors that can mimic a germ cell tumor. The most common are Sertoli cell tumors. They occur as painless masse and usually have no major endocrine effect. Simple orchiectomy is all that is needed. Leydig cell tumors are the second most common stromal tumor. They can be associated with precocious puberty, gynecomastia, and elevated levels of 17-hydroxy ketosteroids. They can be similar to hyperplastic adrenal nodules that are found in boys with poorly controlled congenital adrenal hyperplasia.

Figure 104-18. Testis-sparing enucleation of prepubertal testis tumor with cystic mass seen on the ultrasound and negative markers, likely indicating a teratoma.

Figure 104-19. Histology of prepubertal testis tumor demonstrating mature teratomatous differentiation into ectodermal elements.

Varicocele

Varicocele is a collection of engorged varicose veins in the spermatic cord and usually is most prominent in the scrotum in the region of the pampiniform plexus. Varicoceles are graded according to their size and prominence. Grade I are varicoceles only palpable with exertion or a Valsalva maneuver. Grade II are varicoceles that can be palpated without exertion or a Valsalva maneuver and collapse when supine. Grade III varicoceles are visibly bulging and do not collapse when supine. There is also a subclinical (or grade 0) varicocele that is only detected on imaging and not on physical examination. Varicoceles are most common on the left side comprising >90% of all varicoceles. The left-sided predominance relates to the different nature of the left and right spermatic vein drainage. The right spermatic vein is shorter and inserts directly into the inferior vena cava. About 10% are bilateral. The solitary right varicocele is worrisome as it can be associated with a retroperitoneal tumor and when found warrants further evaluation with abdominal ultrasound. Varicoceles come to attention because of two major concerns. First, they can be quite sizable and uncomfortable. Second, varicoceles are associated in some cases with infertility. This is believed to be the result of two effects. The pooling of venous blood allows toxic waste products to accumulate. The pooled blood in addition may also raise the temperature of the whole scrotum. Normally, the scrotum is several degrees cooler than the deep core body temperature. At random, up to 10% to 20% of all adult males can be found to have some form of varicocele. Among men who attend infertility clinics, varicocele-associated subfertility can be as high as 40%. These observations suggest that there are many men in whom a varicocele is a trivial minor finding, but there are some in whom it can be an important reproductive issue. For boys and adolescence undergoing puberty and sexual maturation, semen analysis findings are variable and unreliable in addition to ethical concerns. For this reason, the clinical indication for intervention in boys is comparative testicular volume on ultrasound. In some, the involved testicle will have a smaller volume or lag in growth. If there is a substantial volume discrepancy (20% or greater) between the testicles, surgery is warranted. If the volumes are stable and there is no major discrepancy, observation with annual ultrasounds is recommended until the age when a semen analysis can be obtained reliably. There are several methods of treating varicocele; the most commonly used approach is via subinguinal or inguinal incision. The vas deferens and spermatic artery are identified and spared. The varicocele veins are then ligated and the segment between the ligatures is removed. The use of an operating microscope allows sparing of the lymphatics thereby reducing the risk of postsurgical hydrocele to well under 1%.

VAGINAL ANOMALIES

Labial Adhesions

Labial adhesions occur when edges of the labia minora attach in the midline and form a thin web of skin (Fig. 104-20). This can obstruct the normal path of the urinary stream leading to postmicturition spotting when the girl stands up. Treatment in very mild cases can be successfully achieved with estrogen cream applied to the surface of the webbing over several weeks. For more severe or refractory cases, surgical incision and separation under anesthesia are needed. Minor adhesion may be left alone without clinical concerns.

Figure 104-20. Labial adhesions.

Figure 104-21. Imperforate hymen.

Imperforate Hymen

Occasionally the hymen will be imperforate at birth. This will present with a bulging hydrocolpos and can be confused with a prolapsing ureterocele or bladder tumor (such as sarcoma) ([Fig. 104-21](#)). Ultrasound or MRI can usually identify the prominent fluid-filled vagina. Puncture and drainage are usually all that is required. In some older patients the condition may not be diagnosed until after the onset of menses. At this time, there may be cyclic discomfort due to the inability to allow the menstrual flow to pass creating a hydrometrocolpos. After a complete workup surgical drainage in the operating room is advisable to avoid introducing bacteria into the sterile collection; an infection can lead to pyocolpos or pyometrium leading to scarring and affecting future fertility.

Urogenital Sinus Anomalies

Between the fifth and seventh week of fetal development the urogenital sinus forms.¹⁹ The caudal portion forms the lower-third of the vagina. The müllerian ducts form the upper two-thirds of the vagina and the uterus as well as fallopian tubes. Anomalies can occur as part of DSD conditions resulting in either vaginal agenesis or urogenital sinus (such as that seen in masculinized females with congenital adrenal hyperplasia). Surgical reconstruction is usually required to create distinct urethra and vaginal channels. Traditional surgical approach aimed at separating the vagina from the UG sinus tract and bringing it down to the perineum, but this often led to vaginal vascular compromise and stenosis. Modern techniques employ urogenital sinus mobilization en bloc, keeping the urethrovaginal confluence intact. Total mobilization has been discouraged due to concern for future urinary incontinence and pelvic prolapse. A combination of partial mobilization – leaving the anterior urethral suspensory ligaments intact – and various perineal flaps can result in an excellent outcome. The Mayer–Rokitansky–Kusterhauser syndrome occurs in normal genotypic females with vaginal and/or uterine dysgenesis. About one-third of these patients will have associated urologic issues – the most common being unilateral renal agenesis. The diagnosis is usually made incidentally or around the age of puberty due to amenorrhea. Treatment is vaginal dilation with estrogen cream or surgical vaginoplasty if dilation fails. There are also a variety of duplication anomalies and vaginal and/or uterine septums and consultation with gynecology is advisable on the necessity and timing of intervention. Typically the goals are to relieve any obstruction to restore normal menses and to preserve reproductive potential.

Figure 104-22. Prune-belly syndrome. Notice the wrinkled appearance of the abdominal wall due to deficiency of musculature. Scrotum is empty due to bilateral intraabdominal testicles.

Prune-belly Syndrome

The prune-belly syndrome (PBS) is a constellation of malformations also known as the triad syndrome or the Eagle–Barrett syndrome.²⁰ The syndrome has three key components: severe deficiency or absence of the abdominal wall musculature, bilateral hydroureteronephrosis, and bilateral undescended intraabdominal testicles (Fig. 104-22). There are also other associated genitourinary conditions including renal dysplasia, fusiform urethra, large bladder, patent urachus, hypoplastic prostate, and dilated proximal urethra. The underlying cause is unknown, but the current theory is that this is triggered by a severe distal urethral obstruction early in development. This theory is supported by the observation of that many of the similar effects are seen in PUVs. The newborn will present with a lax and wrinkled abdominal wall, along with empty scrotum. Renal dysplasia is frequent and when severe, it can lead to pulmonary hypoplasia. Stillbirths and early neonatal demise often occur because of the combination of poor renal and pulmonary function. Hydroureteronephrosis can be massive but is typically nonobstructive, and no procedure should be done simply to improve appearance. Nearly all of the patients are infertile with an anecdotal report of successful fertility using the assisted reproductive technology. For infants who survive into childhood, bilateral orchidopexy and abdominal wall reconstruction may be necessary. Evaluation for bladder function is also required since many will have a poor bladder muscle tone and high post void residual.

10 Neurogenic Bladder

The nervous system plays an important role in modulating the normal behavior of the lower urinary tract. There are nerve roots (emanating from the spinal cord) and peripheral pelvic nerves that carry sensory and motor signals to the bladder and urethral sphincter. Injuries or anomalies to these nerves

can cause the bladder to be denervated, leading to poor emptying. At a higher level, the spinal cord up to the brain stem is critical to regulation of lower urinary tract function, especially the thoracolumbar sympathetic and sacral parasympathetic segments. The brain stem acts as the coordinating center. With filling the bladder musculature – under the influence of the sympathetic input – remains relaxed thereby keeping bladder storage pressures low until emptying occurs (driven by parasympathetic input). The higher centers in the cerebral cortex allow conscious control and inhibition of reflex activity. Without this influence the bladder fills, and at a certain volume it spontaneously empties with coordination. This is what occurs in infants prior to toilet training. When the higher centers are affected (such as due to a cerebrovascular accident, tumor, traumatic brain injury, or multiple sclerosis), this control is lost or diminished and many patients will report sudden urgency and loss of urinary control. When the spinal cord is affected, the bladder will lose its inhibitory control by the brain stem and cerebral cortex and will act autonomously. The bladder will contract earlier than full capacity, and it is termed hyperreflexia. The loss of coordination between bladder muscle and sphincter, leading to poor emptying is known as detrusor–sphincter–dyssynergia.

Patients with spinal cord injury, traumatic brain injury, and acquired conditions that affect the nervous system (e.g., diabetes mellitus, multiple sclerosis, varicella zoster, brain tumors, and encephalitis) should trigger awareness about possible urinary effects.²¹ Mere urine egress from the bladder is not necessarily a sign of normal voiding. It can be due to overflow incontinence or some form of dysfunctional voiding (Valsalva voiding). Likewise continence is not necessarily a sign of neurologically coordinated normal bladder function. The storage pressures can be higher than normal. When the bladder urine storage pressures are too high, it can overcome the peristaltic pressure driving urine from the kidneys down the renal pelvis and ureter. Ideally the storage pressure should be below 40 cm H₂O.²² Above this pressure, hydronephrosis, pyelonephritis, and loss of renal function will occur. A urology evaluation with urodynamic pressure–volume assessment of the lower urinary tract should be considered if there is any condition with significant effects on the central nervous system.

Spina bifida is the most common congenital cause of a neurogenic bladder in children. During development the spinal column does not form properly resulting in an exposed spinal cord, and patients are born with a neurogenic bladder. Surgical closure in utero is now being done in hopes that early closure can lead to better motor and bladder function, although this has not been demonstrated to date. Early evaluation of bladder storage pressures is crucial. Regular, proactive bladder pressure monitoring with cystometrogram, along with ultrasound assessment of the upper tracts, has shown to reduce urologic morbidity in these patients. Children who do not empty with a safe bladder pressure require CIC. Patients with poor bladder compliance and high storage pressures may need antimuscarinic bladder muscle relaxants (such as oxybutynin). For older children, achieving social continence becomes important and a variety of surgical options may be considered in addition to CIC and antimuscarinics. Surgical bladder augmentation using intestinal segments (enterocystoplasty) is the most effective way to improve the bladder storage function (Fig. 104-23), but there are many well-known long-term complications, such as metabolic acidosis, mucus production, UTI, bladder stones, spontaneous perforations, and malignancy. In some patients who have difficulty with urethral CIC (such as those with severe scoliosis or girls in wheelchair), surgical creation of alternate catheterizable neourethra is an option. The Mitrofanoff procedure (the classic appendicovesicostomy where a collapsible supple appendix is implanted into the bladder within the submucosal tunnel for continence) can improve the quality of life significantly. If the bladder outlet is inadequate, surgical options include artificial urinary sphincter, bladder neck reconstruction with sling and bladder neck closure. Similarly, many patients will also choose the surgical option of Malone antegrade continence enema where a catheterizable channel is created into the colon for easy, self-administration of enema for achieving fecal continence.

Figure 104-23. Bladder augmentation using a patch of detubularized ileum.

Chapter 105

Childhood Tumors

Erika Adams Newman

Key Points

- 1 Neuroblastoma is the most common solid tumor in infants and the most common extracranial tumor in all children.
 - 2 Neuroblastoma tumors have diverse clinical heterogeneity from complete spontaneous regression in neonates to resistant metastatic disease in school-aged children. The origin of this disparity is unknown but thought to result from diverse genetic and biologic features that predict prognosis.
 - 3 Several nonrandom segmental genomic alterations have been identified in neuroblastoma as reliable prognostic indicators independent of age and stage. The genomic alterations that have consistently been shown to predict prognosis are DNA ploidy, *MYCN* amplification, loss of heterozygosity (LOH) of chromosome 1p, 17q gain, loss of 14q, and loss of 11q.
 - 4 The International Neuroblastoma Risk Group (INRG) classification system defines pretreatment patient cohorts based on expected survival at diagnosis. INRG classification includes INRG stage, age, histologic category, grade of tumor differentiation, *MYCN* status, 11q alterations status, and DNA ploidy. These criteria are used to define 16 pretreatment groups that include very low-, low-, intermediate-, and high-risk categories.
 - 5 The presence of anaplasia is the single most important prognostic indicator in Wilms tumors.
 - 6 In the United States, the standard of care for children with Wilms tumor starts with radical nephrectomy at the time of diagnosis for resectable primary tumors, followed by chemotherapy. Radiation is administered to sites of residual and metastatic disease. Tumors with extensive intracaval and hepatic vein extension receive neoadjuvant chemotherapy and may require cardiopulmonary bypass for resection.
 - 7 Treatment of rhabdomyosarcoma requires a multimodal approach that begins with complete surgical excision of resectable lesions and incisional biopsy for tumors that encroach upon contiguous structures, blood vessels, and nerves. Modern therapeutic protocols are based on prognostic factors and risk of subsequent relapse stratification.
 - 8 Standard surgical care for children with hepatoblastoma is complete primary resection at diagnosis for PRETEXT I and II tumors that do not involve major central venous structures. PRETEXT III and IV tumors undergo biopsy and neoadjuvant chemotherapy with early referral to liver transplantation for multifocal or large, central lesions.
-

INTRODUCTION

The surgeon is a key figure in the management of the child thought to have a malignant tumor. From diagnosis through posttherapy surveillance, the surgical team plays a pivotal role in ensuring the highest outcomes in the care of children with solid cancers. As a critical component of the pediatric oncology multimodal team, surgical decisions guide clinical pathways from the mechanisms of biopsy, central venous access for chemotherapy administration, and definitive tumor resection. Because pediatric cancers are rare with diverse presentations and histology that differ from adult cancers, the overall care of children with cancer has been improved by multidisciplinary approaches and pediatric cooperative groups that have set the standard in current oncologic care of children. The Children's Oncology Group (COG) and the Societe Internationale d'Oncologie Pediatrique (SIOP) have made significant progress in clinical and basic science studies of pediatric malignancies, and current pediatric tumor care is based upon treatment standards established through phase 1 to 3 clinical-translational trials. It is a universal goal that every child diagnosed with cancer be enrolled in a cooperative group clinical trial. These trials are aimed at further understanding pediatric tumor biology and for evolving

innovative treatments that have recently led to drastic rises in survival rates for various malignancies.

Compared to adults, the classification of childhood cancer is based largely on histologic type and tumor morphology rather than primary site. The current classification scheme is the International Classification of Childhood Cancer, Third Edition (ICCC-3), based on ICD-0-3 (International Classification of Diseases).¹ The ICCC-3 classifies tumors into 12 main groups that are further characterized into 47 subgroups and is used for population-based epidemiologic studies and cancer registries such as the Surveillance, Epidemiology, and End Results (SEER) program, administered by the National Cancer Institute. Utilization of a standard classification system is useful for comparing incidence and survival across regions and time periods.

INCIDENCE OF CHILDHOOD SOLID TUMORS

Each year in the United States, approximately 12,400 children and adolescents younger than 20 years are diagnosed with cancer. Cancer is the most common cause of disease-related mortality in children, with approximately 2,500 children dying each year. Leukemia is the most common cancer diagnosis for children 1 to 5 years of age, 5 to 9 years of age, and 10 to 14 years of age, while neuroblastoma is the most common cancer in infants. For 15- 19-year-olds, lymphomas are the most common diagnosis. Pediatric solid tumors are a spectrum of different malignancies, and behind neuroblastoma, Wilms tumor is the second most common extracranial solid tumor followed by rhabdomyosarcoma (Fig. 105-1). In general, there have been no large increases or decreases in pediatric cancer incidence in the last several decades when improvement in diagnostic modalities such as magnetic resonance imaging (MRI) and ultrasound was taken into consideration.

Figure 105-1. Percentage distribution of childhood solid tumors by age (SEER data, 1975–1995).

In the United States, the cancer survival rate in children has improved over time. This is largely due to multidisciplinary approaches to pediatric oncology care. There have been steady improvements in survival for childhood renal tumors, retinoblastoma, and lymphomas since the beginning of the SEER program. Although mortality rates have declined steadily for nearly all major childhood cancer categories, survival rates for high-risk tumors such as neuroblastoma and rhabdomyosarcoma have not been met with the same survival successes (Fig. 105-2).² Targeted immunotherapies and tumor genomic sequencing are new innovative treatment strategies that have recently provided hope for improving outcomes in resistant and refractory cases.

NEUROBLASTOMA

Epidemiology and Genetic Risk

1 In the United States, approximately 700 children are diagnosed with tumors of the sympathetic nervous system each year and of these, 650 are neuroblastoma. Neuroblastoma is the most common

cancer in infancy and the most common extracranial tumor in all children. The disease accounts for 7.2% of cancers in children younger than 15 years. The incidence of neuroblastoma is slightly higher among males than among females and is highest among Caucasians from North America, Europe, Australia, and Israel.³ The most recent SEER data have reported minimal changes in neuroblastoma incidence in the last five decades. The overall survival rate for neuroblastoma is 65% based upon SEER data from 1985 to 2000, and the disease continues to represent approximately 15% of all pediatric cancer deaths.^{4,5} There is diverse variability in 5-year survival rates based on age and stage. There are no overall differences in survival by race or gender, and survival is highest among infants and patients with localized and regional disease.

Figure 105-2. Survival of most common childhood cancer by type (SEER data, 1975–2005).

No causal factors for neuroblastoma have been identified. Studies examining maternal risks have been conflicting for prior miscarriage, induced abortion, repeat Cesarean birth, and vaginal infection.⁶ There have been international case series reporting the use of maternal hormones for bleeding and ovulation induction. The largest study to date did not find significant association with infertility hormonal use, although results suggested an elevated risk of neuroblastoma in male offspring after maternal Clomid use.⁷ These results warrant further evaluation but may serve as the focus of larger clinical studies. Parental occupation and environmental exposures have been studied.⁸ They suggest that the risk of several industrial occupations, particularly those related to power plant operators, painters, and electronic-related fields, should also serve as lead points for further study. A case-control study investigating parental tobacco smoking and alcohol consumption did not find any evidence for lifestyle exposures and increased risk of neuroblastoma.⁹ Associations between premature delivery (<33 weeks), very low birth weight (<1,500 g), and neuroblastoma have been observed but results are inconsistent.⁶ Further investigations of parental and perinatal risk factors are required in order to draw definitive conclusions.¹⁰

Most cases of neuroblastoma are sporadic and data for inheritance patterns are conflicting. There are studies that link neuroblastoma occurrence with other neural crest cell anomalies such as Hirschsprung disease, neurofibromatosis, and central hypoventilation syndrome.¹¹ These syndromes are components of the neurocristopathies and are considered alterations in neural crest cell development that may occur with inherited loss of function mutations of *PHOX2B*, a regulator of autonomic nervous system development.^{12,13} Despite these findings, there is not a strong pattern of inheritance of neuroblastoma and only 1% to 2% of cases are familial in an autosomal dominant manner.^{14,15} Recently, genome-wide sequencing studies have located heritable mutations in the *anaplastic lymphoma kinase (ALK)* gene as the cause of most hereditary neuroblastoma cases, the first example of a pediatric cancer arising due to a mutation in a critical oncogene.¹⁶ Given this, genetic testing for *ALK* and *PHOX2B* should be considered in children with a family history of neuroblastoma. It is recommended that children in families found to have heritable mutations in *ALK* or *PHOX2B* undergo screening surveillance with ultrasound and urinary catecholamine metabolites.

ALK copy number mutations are also somatically acquired and highly associated with an aggressive clinical phenotype in 5% to 15% of neuroblastoma tumors.^{17,18} Genome-wide association studies in sporadic cases of neuroblastoma have also recently discovered susceptibility genes that include

FLJ22536, *NBPF23*, and *BARD1* that may increase the relative risk of malignant transformation of developing neuroblastic tissue.^{19–22} In general, there is a relative paucity of recurrent somatic mutations in neuroblastoma, and the majority of tumors are likely driven by rare germline variants, copy number alterations, and epigenetic modifications.²²

Pathology and Biologic Features

2 Neuroblastoma originates from embryonic cells of the neural crest that appear along the distribution of sympathetic nervous tissue from the neck to pelvis, most commonly in the adrenal medulla. The precise molecular mechanisms that give rise to embryonic neural crest cells that in turn give rise to neuroblastoma are unknown. The current thinking is that defects in genes that control neural crest differentiation and proliferation underlie neuroblastoma tumorigenesis. Peripheral neuroblastic tumors are categorized on a spectrum from malignant neuroblastoma to ganglioneuroblastoma and benign ganglioneuroma. Neuroblastoma tumors have diverse clinical heterogeneity from complete spontaneous regression in neonates to resistant metastatic disease in school-aged children. The origins of this disparity are unknown but may be explained by a spectrum of genetic and biologic features that are used to stratify patients for treatment.

Figure 105-3. Typical neuroblastoma with small round blue cell feature and Homer–Wright pseudorosettes that palisade around blood vessels.

Neuroblastoma generally occurs in the youngest of children with a median age of presentation of 19 months.²³ The age at which a child is diagnosed with neuroblastoma is an indicator of biologic features and clinical course. Neonates and infants younger than 18 months are more likely to have disease that either spontaneously regresses or is cured without cytotoxic therapy. In contrast, older children are more likely to have refractory metastatic disease and are at high risk for death despite multimodal cytotoxic therapies. Age contributes to prognosis in a continuous manner with the optimal age cutoff between 15 and 19 months.²³ Much of this discrepancy in outcome of neuroblastoma is thought to be associated with underlying tumor biology because there is an association between age and other biologic factors such as *MYCN* amplification and histopathology. Given this, molecular analysis of neuroblastoma tumor specimen is an important factor in treatment planning and in risk stratification.

Cellular heterogeneity is a hallmark of neuroblastoma. Neuroblastic small round blue cells with hyperchromatic nuclei characterize neuroblastoma cells with varying degrees of differentiation from immature to mature. Homer–Wright pseudorosettes that palisade around blood vessels and neuritic processes are characteristic (Fig. 105-3). Neuroblastoma cells stain for neuron-specific enolase, synaptophysin, NB84, and tyrosine hydroxylase, a neural protein staining pattern that differentiates neuroblastoma cells from other childhood tumors with similar small round blue cells.

Treatment strategies for children with neuroblastoma are largely based on risk as determined by histopathologic and biologic characteristics of the tumor. The Shimada histopathologic classification system is the most widely accepted mechanism for microscopic evaluation of neuroblastoma tumors and distinguishes favorable and unfavorable clinical groups. The International Neuroblastoma Pathology Classification System was developed on the basis of the original Shimada system.²⁴ Morphologic features of neuroblastic differentiation, Schwannian stromal development, mitosis–karyorrhexis index (MKI), and patient’s age at diagnosis determine the important distinction between favorable and unfavorable histology (Table 105-1).

In addition to histopathology, combinations of prognostic features are utilized for risk assignment and

treatment stratification in neuroblastoma. The DNA content (DNA index or ploidy) is the amount of DNA within the nucleus of tumor cells compared to normal cells and is an important indicator of treatment success. DNA index is determined by flow cytometry or by cytogenetic analysis. Hyperploidy or near-triploid tumors (DNA index >1) are whole chromosome gains and losses without structural genetic alterations and are associated with a better response to chemotherapy.²⁵ In contrast, diploid tumors are characterized by segmental chromosomal alterations and predict poor response to therapy.

CLASSIFICATION

Table 105-1 Shimada Histopathologic Classification of Neuroblastoma

Favorable Stroma rich, all ages, no nodular pattern Stroma poor, age 1.5–5y, differentiated, MKI <100 Stroma poor, age <1.5 y, MKI <200
Unfavorable Stroma rich, all ages, nodular pattern Stroma poor, age >5 y Stroma poor, age 1.5–5 y, undifferentiated Stroma poor, age 1.5–5 y, differentiated, MKI>100 Stroma poor, age > 1y, MKI >200 MKI, mitosis–karyorrhexis index (number of mitoses and karyorrhexis per 5,000 cells).
Reprinted from Shimada H, Ambros IM, Dehner LP, et al. The International Neuroblastoma Pathology Classification (the Shimada system). <i>Cancer</i> 1999;86(2):364–372. Permission granted for previous edition.

The *MYCN* oncogene is a transcription factor located on chromosome 2p and also predicts survival and risk in neuroblastoma. The amplification of *MYCN* is the best characterized genetic abnormality, occurring in approximately one-third of neuroblastoma patients.^{26,27} Significant amplification of *MYCN* within tumor cells (more than 10 copies detected by fluorescent in situ hybridization) reliably predicts poor survival and advanced-stage disease.²⁸ Although the molecular mechanism of *MYCN* amplification is unknown, targeted expression in transgenic mice leads to the development of neuroblastoma tumors.²⁹ Enhanced expression of *MYCN* increases proliferation and confers growth potential both in vitro and in vivo, adding to the notion that *MYCN* has a critical role in neuroblastoma tumorigenesis.³⁰ Approximately 30% of neuroblastoma tumors have *MYCN* amplification, and of these, 90% are high-stage or refractory to multimodal cytotoxic therapies.³¹

Nerve growth factor (NGF) and its receptor tyrosine kinase (TRK) also correlate with disease outcome in neuroblastoma tumors. The TRK receptors are thought to have a role in regulating growth and differentiation of normal nerve cells and have been implicated in neuroblastoma pathogenesis. The expression of TRK-A, a transmembrane TRK that is required for high-affinity binding of NGF, is strongly predictive of a favorable outcome in neuroblastoma tumors.^{32,33} TRK-B, the receptor for brain-derived neurotrophic factor, is preferentially expressed in neuroblastoma tumors with *MYCN* amplification while TRK-C, the primary receptor for neurotrophin-3 (NT-3), mirrors TRK-A and is expressed primarily in lower-stage tumors with favorable outcomes.³³ The absence or lack of TRK-A correlates inversely with *MYCN* amplification and reliably predicts poor overall survival. Differential expression of TRK-A and TRK-B indicates that NGF receptors may function in growth arrest and differentiation in neuroblastoma tumors, critical factors that may have a role in clinical course.³⁴

3 Several nonrandom genomic imbalances have been identified in neuroblastoma, and the presence of segmental chromosome alterations is the strongest predictor of neuroblastoma relapse.³⁵ The loss of heterozygosity (LOH) of chromosome 1p is a reliable prognostic factor in neuroblastoma tumors that is independent of age and stage. The loss of 1p identifies patients who are at high risk of poor survival outcomes despite otherwise favorable biologic predictors (Stage 1, 2, and 4S disease).³⁶ LOH at 1p is most clinically valuable in predicting patients at high risk of death in the subgroup of patients without *MYCN* amplification, specifically those with low-stage disease.³⁶ Gain at 17q most commonly occurs with loss of 1p in an unbalanced translocation. Unbalanced gain of chromosome arm 17q is the most frequent segmental genetic alteration in neuroblastoma cells and is also associated with adverse outcomes.³⁷ The gain of 17q is strongly associated with other negative risk factors including age of more than 1 year, presence of high-stage disease, *MYCN* amplification, and diploidy. The most likely candidate genes involved at 17q are NM23 and BIRC5 (surviving gene).³⁸ Chromosome 11q loss is found in approximately 40% of patients with neuroblastoma and is associated with high-risk disease features and decreased survival.³⁹ Similar to loss of chromosome 1p, loss of 11q is independently

associated with decreased survival in the subgroup of patients with low-stage disease and in patients without *MYCN* amplification. In all, the genomic alterations that have consistently been shown to predict prognosis are DNA ploidy, *MYCN* amplification, loss of chromosome 1p, 17q gain, loss of 14q, and loss 11q. A systematic review of prognostic tumor markers and meta-analysis showed that of these, *MYCN* amplification and DNA ploidy have the strongest prognostic impact.⁴⁰

Presentation, Diagnosis, and Staging

The majority of children with neuroblastoma are diagnosed at less than 4 years of age, with median age between 19 and 22 months. Forty percent of tumors occur in the adrenal medulla, with the remaining occurring in the neck, chest, abdomen, and pelvis along the sympathetic chain. The organ of Zuckerkandl is the second most common site of neuroblastoma of abdominal origin. Compared to older children, infants are more likely to present with thoracic and cervical primary sites. Tumors at the sympathetic chain along the spinal column may expand into the intraforaminal spaces and can cause spinal cord compression (5% to 15% of patients) (Fig. 105-4). More than half of the patients may present with regional or distant spread through lymphatic and hematogenous routes. Metastatic disease most commonly involves regional lymph nodes, bone marrow, and cortical bone. The most common cortical bone sites are metaphyseal, skull, and the orbit. Patients with orbital bone metastases commonly present with periorbital ecchymosis and swelling (raccoon eyes), and cortical bone metastases may result in generalized bone pain and limping. Liver metastases occur most commonly in patients with stage 4S tumors. Neonates with stage 4S neuroblastoma may present with massive hepatomegaly, respiratory compromise, and abdominal compartment syndrome requiring urgent surgical intervention. Incidental findings on prenatal ultrasound may identify fetal neuroblastoma, and there may be associated maternal signs of catecholamine excess with excessive sweating, headaches, flushing, or anxiety.⁴¹

Most often patients with localized disease are asymptomatic, with tumors diagnosed on routine physical examinations or testing for other medical conditions. In contrast, children may have a mass or abdominal distention as presenting symptoms. There are several well-documented clinical syndromes that can be present at diagnosis of neuroblastoma. Opsoclonus/myoclonus syndrome and/or ataxia can occur in children with neuroblastoma and present as irregular jerking movements of the muscles. The underlying mechanism of opsoclonus is unknown but an immunologic mechanism-related antineuronal antibody is likely, and patients may have late neurologic sequelae despite tumor removal.⁴² The condition may be treated with adrenocorticotrophic hormone, with plasmapheresis and intravenous gamma-globulin reserved for refractory cases.⁴³ Most patients with opsoclonus/myoclonus syndrome tend to have localized disease and excellent survival. Up to 50% of patients with opsoclonus/myoclonus syndrome are found to have neuroblastoma tumors while only a small percentage of patients with neuroblastoma present with opsoclonus. Neuroblastoma tumors that occur in the neck or the upper chest may present with Horner syndrome (ptosis, miosis, anhidrosis), symptoms that may not recover and often worsen with surgical excision.

Figure 105-4. Primary distribution of neuroblastoma tumors in children.

Perinatal Neuroblastoma

The improvement of ultrasound and maternal imaging techniques has increased the diagnosis of neuroblastoma within the fetal and neonatal periods. Most perinatal tumors are located within the adrenal gland and are localized tumors. Upon detection, tumor growth is monitored with serial ultrasound prior to birth, and maternal care proceeds to ensure optimal health of the mother. As long as there are no complications, pregnancy is carried to term. Nearly all perinatal cases have favorable biology without adverse prognostic indicators, including non-*MYCN* amplification. Several lines of evidence suggest that small, localized adrenal tumors detected during the perinatal period may be managed with expectant observation without surgical resection.^{44–46} Given the considerable evidence of spontaneous regression in this subset of neuroblastoma tumors and the risk of adrenal surgery in infants, the COG conducted a prospective trial (ANBL00P2) of expectant observation of infants diagnosed within the first 6 months of life.⁴⁷ This study found that observation of small adrenal masses in infants younger than 6 months, without biopsy and without surgical resection, was safe with excellent event-free and overall survival. Adrenal tumors smaller than 3 cm (16 mL) if solid or 5 cm (65 mL) if $\geq 25\%$ cystic are safely monitored with ultrasound volume measurements, computed tomographic (CT) scan, and urine catecholamine metabolite levels. If there are signs of tumor growth or dedifferentiation, the patient is referred for surgical resection without risk of upstaging of disease.

Diagnosis

The diagnosis of neuroblastoma requires an adequate biopsy specimen and a pathologist experienced with pediatric tumors. The diagnosis is established with histologic confirmation from either tissue biopsy or the presence of tumor cells within a bone marrow biopsy and increased urinary catecholamine metabolite levels.⁴⁸ The majority of patients with neuroblastoma have elevated urinary vanillylmandelic acid and homovanillic acid levels and these should be evaluated during the diagnostic workup. Complete blood count and serum chemistries are evaluated as components of initial diagnostics. Levels of lactate dehydrogenase, ferritin, and neuron-specific enolase are biologic markers that may indicate poor prognosis in patients with neuroblastoma.^{49,50} Elevated ferritin (>150) and lactate dehydrogenase ($>1,000$) may indicate increased risk of adverse outcomes. Seventy percent of patients present with metastatic disease at presentation; therefore, initial evaluation should include cross-sectional imaging by either computerized tomography or MRI to define the primary tumor size and to determine regional or distant spread (Fig. 105-5). Calcifications are commonly detected on imaging in patients with neuroblastoma, and the mass tends to displace structures inferiorly and toward the midline. Unless the patient has neurologic symptoms or an abnormal neurologic examination, lumbar puncture or brain imaging is not indicated. Sympathetic nervous tissue concentrates metaiodobenzylguanidine (MIBG), an analog of norepinephrine. Radioactive iodine-labeled MIBG scan is utilized in neuroblastoma staging and is used to determine treatment response.⁵¹ MIBG scan is accurate in detecting metastatic spread, particularly cortical bone disease that may have otherwise been missed by traditional imaging techniques. Posterior iliac crest aspirates and core biopsies are required as a component of initial diagnostic testing to exclude bone marrow involvement. PET scanning or bone scanning may be utilized in patients with non-MIBG avid disease.

Figure 105-5. Computed tomographic scan of a child with stage 3 neuroblastoma, crossing the midline displacing the aorta, vena cava, kidney, pancreas, and spleen.

Staging

4 The criteria for diagnosis and staging of neuroblastoma have traditionally been based upon the International Neuroblastoma Staging System (INSS). Standard staging criteria allows physicians to tailor treatment plans based on patient risk. INSS is the most widely accepted staging system and was established in efforts to standardize risk-group stratification by cooperative groups (Table 105-2).⁴⁸ Stage 1 is localized tumor with complete gross excision with or without microscopic residual disease and negative ipsilateral lymph nodes. Partially resected tumors and tumors without or with ipsilateral lymph node involvement are either stage 2A or 2B. A tumor that is unresectable or has contralateral lymph nodes involved is stage 3. Any tumor with distant metastases is stage 4. Stage 4S is localized neuroblastoma tumor with distant disease limited to skin, liver, or bone marrow in infants younger than 1 year. Stage 4S is a poorly understood unique subset of neuroblastoma tumors that often spontaneously regress without surgical resection or cytotoxic therapy. INSS is largely based on the surgeon's definition of resectability and surgical approach to the primary tumor and lymph nodes. There is international variation in surgical decision making and approach to locoregional disease that may alter the prognostic value of INSS staging. This has made the performance and comparison of international clinical trials difficult. Moreover, biologic prognostic factors have become increasingly important in treatment planning and risk stratification. To address this, the European International Society of Pediatric Oncology neuroblastoma group proposed radiographic characteristics of the primary tumor as useful predictors of resectability and risk for developing postoperative complications (International Neuroblastoma Risk Group Staging System [INRGSS]).⁵² INRGSS, determines the extent of locoregional disease by the presence or absence of image-defined risk factors (IDRF).⁵³ Stage L1 tumors are localized tumors that are confined within one body compartment and do not involve vital structures or major blood vessels, without any IDRF. L2 tumors are locoregional tumors with one or more IDRF that may involve ipsilateral continuous body compartments and have lower event-free survivals compared to L1 tumors. Stage M is distant metastatic disease and MS is limited to children younger than 18 months with skin, liver, and/or bone marrow metastases. The benefit of INRGSS is that treatment stratification is based on preoperative diagnostic imaging, rather than variable operative approaches. INRGSS now functions as one of the seven prognostic factors in the new International Neuroblastoma Risk Group (INRG) pretreatment classification system.⁵⁴ The INRG classification system defines pretreatment patient cohorts based on expected 5-year event-free survival at the time of diagnosis before treatment. INRG classification includes INRG stage, age, histologic category, grade of tumor differentiation, *MYCN* status, 11q alterations status, and DNA ploidy. These criteria are used to define 16 clinically different pretreatment groups that include very low-, low-, intermediate-, and high-risk categories in terms of 5-year event-free survivals of >85%, >75 to ≤85, ≥50% to ≤75, and <50%, respectively. These clinical categories may further assist physicians and cooperative groups in risk-group stratification based on reliable expected event-free survival cutoffs. Importantly, INRG classification will allow comparison of international risk-based clinical trials with potential to enhance international collaborative efforts.

Treatment

The treatment of neuroblastoma requires a multidisciplinary approach in order to ensure the most optimal outcomes. Treatment is often multimodal with surgery, chemotherapy, radiation, bone marrow/stem cell transplantation, and immunotherapy. Risk group assignment is essential for surgical and medical treatment decisions, as therapies are tailored to risk. Patients are categorized on the basis of INRG classification as very low-, low-, intermediate-, or high-risk. In general, the overall goal is to minimize surgical risks and to limit exposure to chemotherapy in patients with localized disease and favorable biologic features.

In the United States, the current treatment of children with neuroblastoma is guided by protocols established by the COG, and it is recommended that every child diagnosed be enrolled on a clinical trial. ANBL00B1 is the most recently opened COG study that will determine risk stratification and treatment plans based on histology, *MYCN* amplification, ploidy, and serum analysis (<https://clinicaltrials.gov/ct2/show/NCT00904241>). This study will also further investigate other tumor biologic properties including the prevalence of segmental chromosomal alterations 1p, 11q, 14q, and 17q and analyze for independent clinical significance compared to standard prognostic indicators such as *MYCN*, INSS, and age.

STAGING

Table 105-2 International Staging Criteria for Neuroblastoma

Stage	Criteria	Overall Survival (3 Yrs)	Event-Free Survival (3 Yrs)
1	Localized tumor, complete gross resection with or without microscopic margin, all identified ipsilateral and contralateral lymph nodes negative	97%	88%
2A	Unilateral tumor, incomplete resection, negative lymph nodes	87%	72%
2B	Unilateral tumor, incomplete or complete resection, positive ipsilateral but negative contralateral lymph nodes	86%	63%
3	Infiltration of tumor across the midline with or without ipsilateral lymph node involvement; unilateral tumor with contralateral lymph node involvement, midline tumor with bilateral lymph nodes positive	62%	58%
4	Distant metastases to lymph nodes, bone marrow, cortical bone, liver, other organs	<40%	<40%
4S	Localized primary tumor with distant metastatic disease to liver, skin, bone marrow only (<10% involvement), typically neonatal presentation	75%	75%

Very Low Risk and Low Risk

For tumors that are classified as very low risk and low risk with favorable biologic characteristics (INSS stage 1, 2A/2B non-*MYCN*, no 11q alteration), survival rates are >95% with surgery alone without the need for postoperative chemotherapy.⁵⁵ Children with low-risk neuroblastoma are treated on the basis of results of the Children's Oncology Group Study P9641 that demonstrated excellent survival rates in asymptomatic low-risk patients with stages 1, 2a, and 2b neuroblastoma after surgery alone.⁵⁶ The study demonstrated 3-year overall survival of 95% or greater with surgery alone in patients with low-risk, favorable histology disease. The goal of surgery in low-risk patients is complete surgical resection without compromising surrounding organs or blood vessels.

Surgical standards for low-risk neuroblastoma are to establish diagnosis and to resect as much tumor as safely possible without damage to contiguous structures or major blood vessels. Sampling of nonadherent regional lymph nodes and obtaining adequate tissue for biologic studies is critical. Chemotherapy in this group is reserved for patients who relapse or have treatment failure. Chemotherapy is also for patients with less than partial primary tumor resection (<50%), disease that compromises organ function or is life threatening, and patients at risk of developing spinal cord compression. If utilized, low-dose chemotherapy is carboplatin, cyclophosphamide, doxorubicin, and etoposide. Chemotherapy is 6 to 24 weeks depending upon patient's age, weight, and extent of disease. Radiation is seldom given in this group and is reserved for patients with life-threatening symptoms.

Stage MS neuroblastoma tumors without *MYCN* amplification are very low-risk classification and most often spontaneously regress. Children with MS disease require biopsy of either primary or metastatic tumor for biology studies. This subset may be spared for both surgery and chemotherapy. Exceptions are patients with massive hepatomegaly causing abdominal compartment syndrome when low-dose chemotherapy and radiotherapy is given to reduce organ dysfunction. Patients with MS tumors may require decompressive laparotomy and ventilator support. In this case, attempts should be made to biopsy extra-abdominal sites, and diagnosis may also be made by bone marrow biopsy. In rare and extreme life-threatening cases, treatment may be initiated on the basis of diagnostic imaging characteristics alone.

Intermediate Risk

The intermediate-risk group encompasses a broad spectrum of neuroblastoma tumors. The survival rate for patients in this group is between 75% and 90%. All patients in this subgroup receive surgery and chemotherapy. The goals of surgical resection are similar to low-risk cases to establish the diagnosis with enough tissue for histologic and genetic testing with the most complete tumor resection, preserving organ function. If the primary tumor is resectable without damage to surrounding organs and major blood vessels, then full resection is performed with lymph node sampling for staging upfront. Many patients in the intermediate-risk group will have locoregional disease that encroaches upon surrounding organs and major blood vessels (aorta, vena cava, mesenteric vessels, kidney, spleen). The surgeon should defer to the INRG IDRF during assessment for resectability. For L2 tumors with INRG IDRF and those judged to be unresectable at diagnosis, biopsy is performed with plan for neoadjuvant chemotherapy. Delayed surgical resection after four to six cycles of induction chemotherapy minimizes surgical complications and may improve resection of the primary tumor and overall survival.⁵⁷ Moderate-dose chemotherapy for intermediate-risk tumors consists of 12 to 24 weeks of cisplatin,

cyclophosphamide, doxorubicin, and etoposide. The prognosis in this subgroup depends upon patient's age, tumor histology, and biologic properties. Treatment protocols for children with intermediate-risk neuroblastoma are currently based on results of the COG trial A3961. This study demonstrated a high rate of survival with biologically based treatment assignment utilizing substantially reduced duration and doses of chemotherapy agents compared with previously used intensive regimens.⁵⁸ The promising results have reduced cytotoxic therapy for patients with regional disease and favorable biologic characteristics and provided framework for ANBL0531, a COG trial further examining reduction in cytotoxic therapy as more refined risk factors emerge.^{38,59}

High Risk

High-risk neuroblastoma remains one of the most challenging problems in pediatric oncology. Survival in this group remains poor despite multimodal therapy that includes aggressive surgery, intensive cytotoxic chemotherapy, and radiation. The long-term survival is between 10% and 30%. High-risk tumors are characterized by undifferentiated neuroblasts with unfavorable histology and poor prognostic indicators (*MYCN* amplification, 11q alterations, and diploidy). The initial surgical management of high-risk tumors begins with an adequate operative biopsy and vascular access placement. Initial biopsy can be approached by open or minimally invasive techniques including thoracoscopy, laparoscopy, and percutaneous core biopsy. Obtaining an adequate sample size to allow for histologic and cytogenetic studies is of utmost importance and is the primary focus when determining biopsy technique. An initial biopsy should obtain tissue greater than 1 cm³ of viable tumor tissue with avoidance of placement of the specimen in formalin in order to optimize cytogenetic studies. The adequacy of the biopsy specimen should be confirmed with the pediatric pathologist before leaving the operating room. Standard treatment then begins with induction chemotherapy, followed by surgical local control, myeloablative consolidation therapy, and biologic agents.

Induction chemotherapy is administered to improve tumor resectability and to decrease tumor growth. Most neuroblastoma primary tumors and bone marrow are initially sensitive to chemotherapy and will have high response rates. Standard induction therapy consists of combinations of cisplatin, cyclophosphamide, vincristine, doxorubicin, and etoposide. The response rate of induction chemotherapy correlates with survival.⁶⁰ Postinduction persistent bone lesions and bone marrow involvement predict poor overall survival.⁶¹

Local control is achieved with the combination of aggressive surgical resection and external-beam radiotherapy to the primary tumor site. Delayed resection with postinduction chemotherapy excision of as much of tumor as safely possible offers the highest treatment success. After induction chemotherapy consisting of four to five cycles, surgical exploration with the goal of gaining local control of the primary tumor is undertaken. Although the role of primary tumor resection in high-risk patients with neuroblastoma has been controversial, recent studies have shown that aggressive removal of all primary tumors in high-risk patients with neuroblastoma improves survival to 50% and decreases local recurrence to 10%.⁶² Gross total resection of the primary tumor is defined as the removal of all visible and palpable neuroblastomas from the primary tumor site and regional lymph node tissue. The microscopic margin is nearly always positive; therefore, the goal is safe gross total resection with external beam radiation therapy to the surgical bed (2,000 to 2,100 cGy).

Safe tumor dissection typically requires exposure of the great vessels and spine (Fig. 105-6). The incision type depends on the location of the primary tumor with thoracoabdominal or transverse abdominal for large adrenal masses and midline incision for pelvic neuroblastoma. Thoracic neuroblastoma typically has favorable biology and better survival outcomes than abdominal tumors and surgical resection is often curative. Primary thoracoscopic gross total resection is safe in neuroblastoma tumors smaller than 6 cm and may yield surgical and survival outcomes similar to open thoracotomy.^{63,64} Cervical chain tumors may be approached by radical neck incisions and if located at the lower cervical region or apex of hemithorax, a trap-door incision often utilized in the setting of vascular trauma may be applied.⁶⁵ Every effort should be made to preserve the vagus and phrenic nerves. In general, for all neuroblastoma resections, organs and structures should be preserved, particularly the kidney. The operative complications to avoid are excessive blood loss, kidney and renal vessel injury, damage to surrounding major blood vessels or nerves, and postoperative infection and abscess. The tumor is removed by meticulous dissection in the peritumoral capsular plane. Early control of the aorta and the vena cava is essential as the major blood vessels are traced. The major blood vessels often include the celiac axis, superior mesenteric artery, renal vessels, and inferior mesenteric artery. Tightly adherent tumor to blood vessels or major nerves should be left rather than risk injury

though neuroblastoma typically does not invade beyond the adventitia. At times, it is beneficial to divide the tumor over major blood vessels for safe exposure when en bloc resection is not possible at encased blood vessels. Pelvic neuroblastoma typically arises from the organ of Zuckerkandl or elsewhere along the sympathetic chain and is associated with excellent long-term survival, despite residual or microscopic disease. Injuries to the lumbosacral plexus or damage to innervation to the bowel or bladder should be avoided. Selective MRI for pelvic lesions may help define neural involvement and enhance surgical planning. Nerve stimulation may be useful when approaching the pelvic sidewall. The presence of residual tumor correlates with risk of recurrence. Patients with incomplete resection may benefit from higher-dose radiation.⁶⁶

Figure 105-6. Intraoperative depiction of critical exposure during neuroblastoma resection exposing the aorta and the vena cava from bifurcation distal to proximal.

Myeloablative consolidation therapy was investigated in the CCG-3891 study that demonstrated myeloablative therapy with purged bone marrow transplant improved outcome for patients with high-risk neuroblastoma.⁶⁰ The data from this trial have been confirmed with several international studies.⁶⁷ High-dose myeloablative megatherapy (cisplatin, etoposide, cyclophosphamide) with autologous stem cell transplantation improves outcome and progression-free survival compared to maintenance chemotherapy or observation. Over the last several decades, intensification of consolidation therapy with myeloablative doses of chemotherapy, followed by autologous stem-cell rescue has allowed for steady reduction in relapse rates in first remission and has now become standard of care for patients with high-risk disease.⁶⁸ The ability to harvest peripheral blood stem cells along with advances in transplant methodology has enhanced the safety and feasibility of bone marrow transplantation.

Maintenance and biologic therapies have also improved high-risk neuroblastoma treatment. Isotretinoin (cis-RA) is a synthetic retinoid that is now standard of care after induction, local control, and cytotoxic chemotherapy. Currently all patients with high-risk neuroblastoma receive 6 months of high-dose cis-RA therapy after myeloablative therapy and bone marrow transplantation. The COG (ANBL0032) found that the addition of monoclonal antibodies (MAB ch14,18) targeting disialoganglioside GD2 improved survival rates in patients with high-risk disease.^{69,70} GD2 is a sialic acid-containing glycosphingolipid expressed uniformly on the surface of neuroblastoma cells. The Food and Drug Administration recently approved Unituxin (dinutuximab, formerly MAB ch14,18) specifically for the treatment of pediatric patients with high-risk neuroblastoma who achieve at least a partial response to prior first-line multimodality treatment.

Future Directions

Despite advances in cytotoxic and biologic multimodality therapies, up to 60% of patients with high-risk neuroblastoma relapse and there are currently no curative salvage treatment regimens. Advances in understanding neuroblastoma tumor biology are essential for the development of novel therapies for high-risk tumors. The use of high-throughput genomic sequencing technologies will aid in patient-specific prognostic data and allow for a personalized approach to treatment. The success of anti-GD2 monoclonal antibody has launched great interest and research into improving antibody-based approaches and synergistic immunotherapies. A recent study showed promise in humanized anti-GD2 engineered to target the delivery of interleukin-2 to tumor microenvironment in patients with small tumor burden.⁷¹ The addition of MAB ch14,18 and cytokines granulocyte/macrophage colony-

stimulating factor and interleukin-2 to cis-RA may prevent late relapse. Radiolabeled MIBG is also being investigated as a therapeutic agent in neuroblastoma and has a high response rate in patients with relapse and refractory disease.^{51,72,73} Targeted radionucleotide has little nonhematologic toxicity though most patients experience some level of myelosuppression requiring autologous hematopoietic cell transfusion.

The challenges also remain the ability to identify patients with low-risk and intermediate-risk tumors who benefit from reduction in therapy versus those who are at risk for relapse and refractory disease. There are several large collaborative research efforts focusing on the discovery of new therapeutic targets with respect to understanding the relationship between risk and the molecular basis of neuroblastoma. One such effort is the Therapeutically Applicable Research to Generate Effective Treatments (TARGET) program (<http://target.cancer.gov>). TARGET in conjunction with the Cancer Genome Atlas project conducts genomic profiling and tumor sequencing for neuroblastoma along with other pediatric solid tumors with the goal of discovering novel mechanisms that drive tumorigenesis and identifying new molecular targets for drug development.

WILMS TUMOR

Epidemiology and Genetic Risk

Various tumors arise in the kidneys in children that range from benign to malignant. Wilms tumor (nephroblastoma) is the most common renal tumor in children and is the second most common solid tumor outside of the brain in infants behind neuroblastoma. Wilms tumors occur almost exclusively in the kidney. Extremely rare extrarenal sites include the retroperitoneum, pelvis, and inguinal canal.⁷⁴ The overall incidence of Wilms tumor is eight per million children younger than 15 years, with approximately 500 new cases per year in the United States.⁴ Children most commonly present within the first 2 years of life, with nearly all diagnosed before the age of 5 years. The incidence of Wilms tumor varies by ethnicity with highest incidence in Africa and African-American children and lowest in East Asian populations.⁷⁵ The National Wilms Tumor Study (NWTs) reported that the median age for Wilms tumor in boys is 36 months and 43 months for girls with unilateral tumors.⁷⁶ Bilateral Wilms tumors occur in slightly younger children with median ages of 23 months for boys and 30 months for girls. The survival of children with Wilms tumor has improved significantly over the past several decades from 30% to more than 90% 5-year survival currently.⁷⁷

Table 105-3 Syndromes Associated with Increased Susceptibility to Wilms Tumor

Syndrome	Gene	Phenotype
WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation)	<i>11p13/WT1</i> : deletions, <i>PAX6</i>	Absence of iris, genitourinary defects, mental retardation; 30% develop Wilms tumors
Denys–Drash	<i>11p13/WT1</i> : point mutations	Genitourinary defects, renal mesangial sclerosis and intersex disorder; 90% develop Wilms tumors
Frasier	<i>11p13/WT1</i> : point mutations	Genitourinary defects, focal glomerular sclerosis, and intersex disorder; rarely develop Wilms tumors
Beckwith–Wiedemann	<i>11p15</i> : several genes (<i>IGF2</i> , <i>H19</i> , <i>p57</i> , and <i>LIT1</i>)	Organomegaly including tongue, hemihypertrophy, hypoglycemia, umbilical hernia, increased risk of tumors (Wilms tumor, hepatoblastoma, adrenal carcinoma); 5% develop Wilms tumors
Simpson–Golabi–Behmel	<i>Xq26/GPC3</i> : point mutations, microdeletions	Organomegaly, renal dysplasia, excess digits, diaphragmatic and heart defects; 7.5% develop Wilms tumors
Sotos	<i>5q35/NSD1</i> : point mutations, microdeletions	Overgrowth, craniofacial dysmorphism, mental retardation, and increased risk of tumors (Wilms tumor, neuroblastoma, acute lymphocytic leukemia); 5% of patients develop Wilms tumor
Perlman	Unknown	Macrosomia, visceromegaly, cryptorchidism, excess amniotic fluid, characteristic facial features; 30% of patients develop Wilms tumors
Familial Wilms tumor 1	<i>17q12–21</i>	20% of patients develop Wilms tumors
Familial Wilms tumor 2	<i>19q13,4</i>	70% of patients develop Wilms tumors

GPC3, glypican 3; *IGF2*, insulin-like growth factor 2; *NSD1*, nuclear-receptor-binding SET-domain protein 1; *PAX6*, paired box gene 6; *WT1*, Wilms tumor protein 1.
Reprinted from Rivera MN, Haber DA. Wilms' tumour: connecting tumorigenesis and organ development in the kidney. *Nat Rev Cancer* 2005;5(9): 699–712.

Most Wilms tumors are sporadic with only 1% to 2% of cases being familial. Several genetic syndromes are uniquely associated with Wilms tumor. Sporadic aniridia, hemihypertrophy, genitourinary tract abnormalities, and Beckwith–Wiedemann syndrome are known to be associated with an increased risk of Wilms tumor in children.⁷⁸ The study of patients with sporadic aniridia and Beckwith–Wiedemann syndrome led to the discovery of WT1, a tumor suppressor gene located on chromosome 11p necessary for normal renal development.^{79,80} Inactivating mutations lead to the development of most Wilms tumors, and germline mutations account for most of the syndromic anomalies that are associated with chromosome 11 including WAGR (Wilms tumor, aniridia, genitourinary abnormalities, intellectual disability), Denys–Drash syndrome (pseudohermaphroditism, glomerulopathy, renal failure, Wilms tumor), and Beckwith–Wiedemann syndrome.⁸¹ Inactivating point mutations in the *WT1* gene, located on chromosome 11p13, are associated with Denys–Drash syndrome, and LOH at the 11p15 locus (WT2) is found in Beckwith–Wiedemann syndrome, with 5% to 10% of patients having Wilms tumors.⁸² Patients with WAGR syndrome have associated somatic germline mutations of 11p13. FWT1 (17q) and FWT2 (19q) have been identified in familial Wilms tumor disposition (Table 105-3).⁸³ Table 105-3 lists known genetic syndromes associated with increased susceptibility to Wilms tumor.

Pathology and Biologic Features

5 Wilms tumors arise from pluripotent developmental renal precursor cells. In most cases, only one kidney is affected but may present as bilateral disease in up to 6% of children. Multicentric disease is found in 7% of patients. Wilms tumors arise within the renal medulla and cortex and may invade renal calyces, renal vein, and inferior vena cava. The tumor is most commonly a well-circumscribed mass with a fibrous capsule. The most common sites of metastatic spread are lungs, lymph nodes, and liver. Wilms tumors are composed of a classic triphasic combination of blastemal, stromal, and epithelial cells. Characterization of histologic subtype is critical for risk stratification and for treatment planning. Blastemal predominance may indicate a high-risk category of patients with increased risk of recurrence.⁸⁴ Importantly, anaplastic cells characterize 7% of Wilms tumors and are defined by the presence of enlarged nuclei and hyperchromasia with multipolar polypoid mitotic figures (Fig. 105-7).⁸⁵ Compared to tumors without anaplasia, anaplastic Wilms tumors are generally found in older children and are more likely to have lymph node metastases. Differences in race are also observed with African or Latin-American children having the highest proportion of tumors with anaplasia. Tumors with diffuse anaplasia (present in more than one area of the tumor or extrarenal sites) are defined “unfavorable histology” and have higher resistance to chemotherapy than tumors without anaplasia.⁸⁶ The single most important prognostic indicator in Wilms tumors is the presence of anaplasia.

Clear cell sarcoma and rhabdoid tumor of the kidney are also unfavorable histologic subtypes and are now considered distinct entities from Wilms tumors.^{77,87} Nephrogenic rests represent the persistence of developmental renal tissue in the kidney after the 36th week of gestation and 1% undergo malignant transformation to Wilms tumor. Two major categories of nephrogenic rests have been characterized, perilobar and intralobar, distinguished by their position within the renal lobe.⁸⁰ Nephrogenic rests are considered precursor lesions of Wilms tumor and are found in nearly half of cases.⁸⁸ Intralobar characterizes early developmental disturbances and occurs in aniridia and Denys-Drash syndrome, while perilobar develops later in nephrogenesis and occurs in patients with Beckwith–Wiedemann syndrome and hemihypertrophy. Nephroblastomatosis is the term used to describe the presence of diffuse nephrogenic rests and typically involves both kidneys. The presence of nephrogenic rests demonstrates the vast degree of heterogeneity in Wilms tumor biology as they either involute or progress to hyperplastic overgrowth or neoplastic induction.⁷⁷ Patients with nephrogenic rests are at risk for bilateral kidney involvement that decreases with age.

Figure 105-7. Microscopic examination of Wilms tumor showing highly cellular areas composed of undifferentiated blastemal cells with loose surrounding stroma with undifferentiated mesenchymal cells and immature tubules. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999, permission granted with previous edition.)

Several biologic factors have been identified in Wilms tumors that associate with risk. Tumor-specific LOH at chromosomes 1p and 16q are independent prognostic indicators and are associated with greater risk of relapse and mortality. The fifth National Wilms Tumor Study Group trial (NWT5-5) found that tumors with LOH at 16q had an adverse effect on prognosis with relapse rates three times higher and mortality rate 12 times higher than those without LOH at chromosome 16q.⁸⁹ Patients with LOH for chromosome 1p also had relapse and mortality rates higher than those without LOH at 1p.⁹⁰ LOH for both chromosomes 1p and 16q are found in up to 5% of Wilms tumors.

Presentation, Diagnosis, and Staging

Children may present with a palpable asymptomatic abdominal mass identified by parents or pediatrician during well-visit examination. If present, symptoms may include intermittent abdominal pain, gross or microscopic hematuria (25% of patients), and hypertension (25% of patients). Hypertension occasionally results from either an increase in renin secretion by the tumor or by compression of the renal artery by tumor mass effect. Intraparenchymal bleeding and preoperative rupture may occur causing systemic symptoms of fever and anemia. The mass is typically nontender and nonmobile on physical examination. The child should be examined for aniridia, macroglossia, hemihypertrophy, and genitourinary abnormalities. Signs of intravascular spread may present as ascites, hepatosplenomegaly, and cardiac murmur. Standard complete blood count and serum chemistries should be assessed though renal function is usually unaffected. Red blood cells may be present on urinalysis.

The diagnostic imaging workup is initiated with abdominal ultrasound and CT scan with oral and intravenous contrast. CT scan is the standard imaging modality that will provide information about mass location, size, extent of tumor invasion, and involvement of the contralateral kidney (Fig. 105-8). Critical examination of renal vasculature and intracaval extension is evaluated by Doppler ultrasonography. A good posteroanterior and lateral chest radiograph is obtained to determine the presence of lung metastases. It is critical to determine whether a patient with Wilms tumor has lung metastases because these patients are assigned to higher disease stage and receive radiation to the lungs and more intensive chemotherapy. There is considerable controversy regarding the utilization of chest CT scan versus plain chest radiograph to detect lung metastases in patients with Wilms tumor because of interobserver variability in interpretation.⁹¹ If utilized for staging workup, chest CT should be performed with standardized techniques and interpretation through a central review process considered. Pulmonary metastases identified on chest CT but not on plain chest radiograph may identify a subgroup of patients at increased risk of pulmonary relapse.⁹² It may be beneficial to obtain histopathologic confirmation of pulmonary metastases by surgical biopsy given the potential for upstaging and radiotherapy.⁹³

In the United States, nephrectomy follows the initial diagnostic workup, allowing the combination of surgical and histologic parameters to be included in staging at diagnosis. During the procedure, the surgeon must determine tumor extent, tumor rupture, and the status of regional, paraaortic, and paracaval lymph nodes. Distant metastatic disease should also be determined by inspecting the peritoneal surfaces, diaphragm, and liver. The COG no longer recommends direct visualization and manual palpation of the contralateral kidney as long as the contralateral kidney is clear of tumor on cross-sectional imaging.

The staging of Wilms tumor is based on the anatomy of the tumor and lymph nodes as detailed by the

NWTSG staging system. The staging system incorporates clinical, surgical, and pathologic information and allows stage-based approach to treatment to minimize exposure to cytotoxic agents (Table 105-4). Stage 1 tumors are limited to the kidney and completely resected with an intact renal capsule without involvement of the renal sinus vessels. Stage 2 tumors extend beyond the kidney by either penetration of the renal capsule or invasion of sinus vessels. Biopsy before removal or local tumor spillage is classified as stage 3. Tumors that are unresectable or incompletely resected with positive margins are also stage 3 tumors. Tumors with regional lymph node metastases are stage 3 criteria as well. Stage 4 tumors have distant spread (liver, lung, bone, brain) or lymph node spread outside of the abdomen. Bilateral Wilms tumors are classified as stage 5 though precise staging for patients with bilateral Wilms tumor is based on local stage for each kidney. Advanced tumor stage at diagnosis predicts an increased risk of recurrence and tumor rupture at surgery predisposes to relapse.⁹⁴ Older age is also an adverse prognostic factor and predicts disease recurrence.⁹⁵ Tumor stage and histology are the most significant prognostic factors for children with Wilms tumor.

Treatment

Most children diagnosed with Wilms tumor are cured by multimodal therapy. Much of the success in therapy is the result of collaboration and research trials conducted by three cooperative groups, the NWTSG, now a part of the COG, the United Kingdom Children's Cancer Study Group (UKCCSG), and the SIOP. In the United States and Canada, nearly all children are treated according to protocols established by the NWTSG. The primary goals of therapy are to treat on the basis of well-defined risk groups and to achieve the highest cure rates with minimal toxicity.

Figure 105-8. A: Abdominal CT scan with left Wilms tumor displacing midline organs and vessels, rim of kidney enhancing at lateral border. B: Intraoperative view of right Wilms tumor arising from retroperitoneum, displacing colon and midline structures, approached via a generous right supraumbilical transverse abdominal incision.

6 Surgery is a critical component of local primary tumor control and treatment outcomes. In the United States, the standard of care starts with radical nephrectomy at the time of diagnosis of resectable primary tumors, followed by chemotherapy and radiation to sites of residual and metastatic disease. Preoperative chemotherapy is given to patients with inoperable tumors, bilateral disease, solitary kidney, and for tumors with intravascular extension above the hepatic veins. A significant number of patients are downstaged after preoperative chemotherapy without altering recognizable anaplasia.⁹⁶ In contrast to this treatment approach, SIOP therapy begins with chemotherapy administration for several weeks prior to nephrectomy in all patients presenting with Wilms tumors.⁹⁷ The standard chemotherapeutic drugs with activity against Wilms tumors are vincristine and actinomycin-D. Doxorubicin is added to patients with stage 3 tumors and to those with unfavorable histology or adverse biologic prognostic markers such as LOH at chromosome 1p or 16q. Combinations of cyclophosphamide, ifosfamide, carboplatin, and etoposide are utilized for select stage 3 and 4 cases with

unfavorable biology and for resistant or relapsed cases. In the United States, the optimal combination, duration, and mode of administration of chemotherapy are optimized through clinical trials and studies of the NWTSG and COG.

The first two NWTSG, NWTSG-I and NWTSG-II, found that routine postoperative radiation was unnecessary in patients with tumors confined to the kidney and completely resected. Combination therapy of vincristine and actinomycin-D was more effective than single-agent therapy, and the addition of doxorubicin improved survival in higher-stage patients. In addition, the duration of combination chemotherapy was successfully reduced in low-stage patients from 15 months to 6 months without compromising survival outcomes.^{98,99} These studies established criteria that identify unfavorable (anaplasia) and favorable histologic features that stratify patients into high-risk and low-risk treatment groups. High-risk patients are at a higher risk of recurrence and also include those with unresectable tumors, lymph node metastases, and diffuse tumor spill. This patient group benefits from intensified chemotherapy and abdominal radiation. These findings paved the way for NWTSG-III that demonstrated successful treatment of stage 1 favorable histology Wilms tumors with lower dosing and further reduced duration of vincristine and actinomycin D. The 4-year relapse-free and survival rates with this regimen were 89% and 95%.¹⁰⁰ This study found that stage 2 patients with favorable histology were treated successfully with vincristine and actinomycin D without postoperative radiotherapy or doxorubicin, and stage 3 patients had no differences in abdominal recurrence with reduction of abdominal radiotherapy compared to patients with high-dose radiotherapy when doxorubicin was administered (10.8 Gy compared to 20 Gy). The NWTSG-III also found that patients with stage 4 favorable histology tumors were successfully treated with vincristine, actinomycin D, doxorubicin and local radiotherapy based on local tumor stage. The addition of cyclophosphamide was without benefit. This group received lung radiation to both lungs (12 Gy), with 4-year relapse-free and overall survival of 79% and 80.9%. The NWTSG-IV trial was largely based on improving treatment results through modifying drug administration utilizing shorter and “pulse-intensive” chemotherapy regimens compared to standard divided dose regimens.¹⁰¹ The results of this study revealed that shorter pulse-intensive regimens were equivalent to standard treatment regimens in terms of overall survival with total chemotherapy duration of 6 months. Since the NWTSG-IV trial, survival rates for children with Wilms tumor have steadily improved with shorter chemotherapy schedules and lower treatment costs.¹⁰² Based on results of NWTSG-IV, the current overall survival rate for children with favorable histology Wilms tumor approaches 90%. Current 10-year relapse and overall survival for stage 1 favorable histology Wilms tumors are 91% and 96%, and for stage 2 tumors, 85% and 93%, respectively.¹⁰³ NWTSG-V completed enrollment in 2003 and was designed as a nonrandomized single arm therapeutic trial to treat patients with stage- and histology-specific treatment plans. In this study, patients were not randomized to therapy, rather biologic properties of tumors were assessed. The aims included determining whether tumor LOH for chromosomes 1p and 16q was associated with poorer prognosis in patients with favorable histology Wilms tumors and to determine whether increased DNA content in tumor cells was associated with adverse outcomes.¹⁰⁴ LOH for 1p and 16q identified a subgroup of favorable histology patients who have a significantly increased risk of relapse and death.⁹⁰ LOH for these chromosomes is now used as an independent prognostic factor as patients with LOH for chromosome 1p and 16q have 75% relapse-free survival.

STAGING^a

Table 105-4 Wilms Tumor Staging System

Stage	Criteria	4-Yr Survival Rate (%)
1	Tumor is limited to kidney, completely excised; no evidence of rupture, intact surface	97
2	Tumor extends beyond kidney but completely excised, infiltration through renal capsule, extension into vessels outside kidney, local or open biopsy or spillage confined to flank, no residual tumor	95
3	Residual nonhematogenous tumor	91
4	Hematogenous metastases to lung, liver, cortical bone, brain, other organs	78
5	Bilateral renal involvement at diagnosis	Same as highest unilateral stage

^aSurvival based on outcome from patients with favorable biology in the National Wilms Tumor Study-3. Courtesy of the National Wilms Tumor Study.

The NWTSG-V also attempted to verify that surgery alone may have acceptable overall survival rates in a subgroup of children younger than 2 years at diagnosis with very low-risk favorable histology of

Wilms tumors that weigh less than 550 g.¹⁰⁵ The incidence of relapse was higher in this subgroup of patients receiving surgery only, but the salvage rate was surprisingly high with long-term survival being the same as patients receiving conventional postoperative chemotherapy. Given this, cooperative group trials will further study optimal management of surgery alone in this subgroup to determine whether very low-risk patients may be spared adjuvant therapy.

Since 2006, the COG has opened four clinical trials for the treatment of children with Wilms tumors. For these therapeutic studies, patients are stratified into very low-risk, low-risk, standard-risk, and high-risk groups on the basis of tumor histology, stage, biologic assessment, tumor weight, and age. To facilitate accurate risk assessment, it is currently recommended that all patients diagnosed with Wilms tumor be enrolled and follow protocol recommendations of AREN03B2, a biology classification-based trial. The current treatment recommendations are summarized in [Table 105-5](#) and are based on the most recent COG trials developed to build upon and refine results of previous NWTs ([Table 105-5](#)).¹⁰⁶ The protocol guidelines recommend that stage 1 and 2 favorable histology patients undergo initial nephrectomy and lymph node sampling, followed by vincristine and actinomycin-D chemotherapy (regimen EE-4A). Doxorubicin (regimen DD-4A) is added to the treatment plan in patients with stage 1 and 2 tumors with favorable histology and LOH at chromosome 1p and 16, as this subgroup has been shown to have an increased risk of relapse and death. Stage 1 tumors with unfavorable histology (focal or diffuse anaplasia) have lower 10-year relapse-free and overall survival of 69% and 82% and are treated with vincristine, actinomycin-D, doxorubicin (regimen DD-4A), and abdominal radiotherapy. Stage 3 patients with favorable histology are treated with nephrectomy, lymph node sampling, vincristine, actinomycin-D, and doxorubicin (regimen DD-4A) and abdominal radiotherapy, with 10-year relapse-free and overall survival of 84% and 89%. Cyclophosphamide and etoposide (regimen M) are added to the treatment regimen for stage 3 tumors with favorable histology and LOH at chromosomes 1 and 16q. The presence of diffuse anaplasia also intensifies therapy in stage 2 and 3 tumors with the addition of cyclophosphamide, carboplatin, and etoposide for 30 weeks (regimen UH-1) and abdominal radiotherapy, with 10-year and overall survival rates of 43% and 49%. Stage 4 patients with favorable histology and pulmonary metastases are treated with nephrectomy, lymph node sampling, and vincristine, actinomycin-D, and doxorubicin for 24 weeks. In patients with stage 4 disease, the primary tumor is staged separately to determine the requirement for abdominal radiation. Lung radiotherapy is currently utilized if metastases remain detectable after 6 weeks of chemotherapy. For these reasons, it remains advantageous to resect the primary tumor prior to the initiation of chemotherapy even in patients with stage 4 disease. Based on results of NWTs-4, the 10-year relapse-free and overall survival for patients with stage 4 favorable histology Wilms tumor is 75% and 81%. Stage 4 favorable histology tumors with LOH at chromosomes 1p and 16q are treated with the addition of cyclophosphamide and etoposide (regimen M) and abdominal radiation. Stage 4 tumors with focal or diffuse anaplasia (without measurable disease) are treated with the addition of cyclophosphamide, carboplatin, and etoposide for 30 weeks (regimen UH-1) and radiotherapy. This subgroup of patients has the worst 10-year relapse-free and overall survival of 18%. Stage 5 Wilms tumors (bilateral tumors) with favorable histology have 10-year relapse-free survival and overall survival of 65% and 78%. Patients with bilateral Wilms tumors are treated with preoperative chemotherapy (vincristine, actinomycin-D, doxorubicin) and renal-sparing surgery.

Table 105-5 Recommended Therapy According to COG Protocols

Stage/Histology	Radiotherapy	Chemotherapy
Stage I FHWT, <2 yo, <550 g	None	None
Stage I FHWT, >2 yo, >550 g	None	Regimen EE-4A
Stage II FHWT	None	Regimen EE-4A
Stage I, II FHWT, LOH 1p, 16q	None	Regimen DD-4A
Stage III FHWT, no LOH 1p, 17q	Yes	Regimen DD-4A
Stage I-III focal AHWT	Yes	Regimen DD-4A
Stage I diffuse AHWT	Yes	Regimen DD-4A
Stage III, IV FHWT LOH 1p, 16q	Yes	Regimen M
Stage IV FHWT, pulmonary metastases		
Lesions resected at diagnosis	Yes	Regimen DD-4A
Lesions resolve after 6 weeks chemo	None	Regimen DD-4A
Lesions persist after 6 weeks chemo	Yes	Regimen M
Stage IV FHWT nonpulmonary metastases	Yes	Regimen M
Stage II-III diffuse AHWT	Yes	Regimen UH-1
Stage IV diffuse AHWT	Yes	Regimen UH-1

AHWT, anaplastic histology Wilms tumor; AMD, dactinomycin; CYCLO, cyclophosphamide; DOX, doxorubicin; ETOP, etoposide; FHWT, favorable histology Wilms tumor; LOH, loss of heterozygosity; regimen DD-4A, pulse-intensive AMD, VCR and DOX (24 weeks); regimen EE-4A, pulse-intensive AMD plus VCR (18 weeks); regimen M, VCR, AMD, DOX, alternating with CYCLO and ETOP (24 weeks); regimen UH-1, CYCLO, carboplatin, ETOP alternating with VCR, DOX, CYCLO (30 weeks); VCR, vincristine.

Surgical Considerations

Preoperative biopsies are contraindicated unless a tumor is judged unresectable. For most patients, unilateral radical ureteronephrectomy with abdominal exploration is accomplished through a wide transverse abdominal incision that will allow safe resection and regional lymph node sampling without rupture. A thoracoabdominal incision may be utilized as necessary for tumors reaching the diaphragm. Complete abdominal and pelvic exploration is performed. The contralateral kidney does not require exploration if preoperative imaging does not suggest involvement. The lateral peritoneal reflection is incised and the colon is reflected medially. Although a formal retroperitoneal lymph node dissection is not recommended, lack of adequate lymph node sampling along with the primary tumor resection automatically upstages treatment to stage 3 disease because of the risk of local relapse.¹⁰⁶ Gentle handling of the tumor is critical to avoid tumor rupture and spillage as there is a sixfold increase in local relapse and also automatic tumor upstaging to stage 3.¹⁰⁷ Both local and diffuse tumor rupture will increase relapse risk. It is often unsafe to attempt to ligate the renal vein prior to tumor manipulation given the size of most Wilms tumors as traditionally recommended by most authors. Later ligation of the renal vein after tumor mobilization has not been shown to adversely affect survival outcomes, and early ligation should not be attempted if technically difficult. The dissection is carried out along the tumor capsule and outside of Gerota fascia identifying the renal hilum and isolating the renal artery, vein, and the ureter (Fig. 105-9). The renal vein and inferior vena cava are palpated for intravascular tumor extension. The ureter is divided as distal as possible to the renal hilum though it is not necessary to remove the entire ureter. The tumor and the kidney are then removed en bloc. The adrenal gland may be left in place if it does not abut the tumor or if the tumor arises from the lower pole of the kidney.¹⁰⁸ Titanium clips should be utilized to identify any gross residual tumor. The tumor and the nephrectomy specimen should not be placed into fixative but delivered fresh and sterile to the pathologist to optimize histologic and cytogenetic analysis based on pediatric tumor protocols.

There have been reports of laparoscopic resection of Wilms tumor.¹⁰⁹ These are more likely feasible after preoperative chemotherapy with lower risk of tumor rupture, though safety has not been confirmed. Success of laparoscopy for Wilms tumor is hindered by tumor spill and by inaccurate staging.

Patient selection for preoperative chemotherapy is a critical step in surgical and treatment planning. The overall incidence of surgical complications in patients undergoing nephrectomy for Wilms tumor is 12.7%.¹¹⁰ The most common surgical complications are small bowel obstruction (5.1%) and excessive hemorrhage (1.9%), followed by wound infection (1.9%) and vascular injury (1.5%) as reported by the NWTs-IV trial. Higher-stage tumors, intravascular extension, and resection of contiguous organs are risk factors associated with surgical complications. The risk of renal insufficiency after unilateral nephrectomy for Wilms tumor is low (0.25%), and patients with Denys-Drash syndrome are most at risk for progressive tumor in the remaining kidney.¹¹¹ For these reasons, nephron-sparing procedures are currently reserved for children with bilateral Wilms tumor and for those at risk for developing renal failure and not indicated for patients with standard unilateral tumors with a normal contralateral

kidney.

Figure 105-9. Anatomy and operative approach to resection of a Wilms tumor.

Renal Vein/Inferior Vena Cava

Four percent to 10% of patients with Wilms tumor have intravascular extension into the renal vein, inferior vena cava, and rare cases extending into the atrium. Patients may have symptoms of vascular involvement depending on the degree of venous obstruction that may include hypertension, hepatosplenomegaly, ascites, and heart failure. The preoperative ultrasonography and CT scan are accurate in detecting intravascular tumor extension, but the vessels should still be palpated prior to ligation of the renal vein during tumor excision. Studies of Wilms tumors with intravascular extension have found that preoperative chemotherapy facilitates resection by decreasing the extent of tumor thrombus. Overall frequency of complications and the 3-year relapse-free survival rates were similar between the preoperative therapy group and the upfront resection group.¹¹² Control of the renal vessel and vena cava below and above the tumor thrombus is essential to obtain vascular control and to minimize bleeding after venotomy. Effort should be made to avoid transecting tumor thrombus. If the patient has intracardiac tumor extension after preoperative chemotherapy, a combined thoracoabdominal incision with cardiopulmonary bypass is the safest surgical approach for tumor thrombus excision. The overall survival of children with intravascular extension is the same as children with disease limited to the kidney of similar stage and histology.¹¹³

Bilateral Wilms Tumor

Five to eight percent of patients with Wilms tumors present with bilateral disease. Bilateral Wilms tumor is found more frequently in patients with hemihypertrophy and genitourinary anomalies. Primary tumor excision at diagnosis is discouraged and patients may be enrolled on NWTs trials without an initial biopsy. If obtained because of uncertainty in diagnosis, core needle biopsies through a posterior approach are preferable to minimize contamination of the abdominal cavity and three-drug chemotherapy is initiated. All children with bilateral Wilms tumors should receive preoperative chemotherapy with the goal of renal preservation. The current COG protocol recommends reevaluation by abdominal CT scan after 6 weeks of chemotherapy to determine the feasibility of a renal-sparing procedure. If the tumor response is less than 50% shrinkage, the COG recommends bilateral open renal biopsies to assess tumor histology prior to additional chemotherapy. After 12 weeks of therapy, all patients should undergo surgical resection as continuing therapy beyond 12 weeks has not been shown to improve outcomes. The primary surgical goal is to spare as much renal parenchyma as possible while obtaining complete tumor resection. Children with synchronous bilateral Wilms tumor or tumor with contralateral nephrogenic rests that have complete radiographic response may not require surgical excision and have low risk for local relapse.¹¹⁴ These children are monitored for recurrence by serial imaging. If partial nephrectomy is not safe after 12 weeks of chemotherapy, then nephrectomy is recommended. In NWTs-IV, children with bilateral Wilms tumor who had partial resection with

complete resection of all gross disease had local relapse rate of 8% and 4-year overall survival of 81.7%.¹¹⁵

Partial Nephrectomy

Nephron-sparing surgery is utilized in patients with bilateral Wilms tumor and in select patients at high risk for bilateral disease or renal failure. Partial nephrectomy is not indicated in patients with standard unilateral Wilms tumor given the low risk of renal failure with unilateral nephrectomy. Children with Wilms tumor predisposing syndromes such as WAGR, Beckwith–Wiedemann syndrome, and Denys–Drash syndrome are predisposed to the development of tumors in the contralateral kidney and are, therefore, managed with a nephron-sparing partial nephrectomy approach for unilateral tumors. Screening imaging studies in such patients at risk of developing Wilms tumors may detect lesions that are appropriate for nephron-sparing procedures. These patients may still benefit from preoperative chemotherapy to minimize the extent of renal resection. A radionuclide dimercaptosuccinic acid renal scan (DMSA scan) is useful to assess preoperative and postoperative renal function.

Partial nephrectomy is typically feasible only if tumor involves one pole and less than one-third of the kidney and if the collecting system and renal vein are uninvolved. For bilateral tumors, the kidney with the lowest tumor burden is addressed first to determine whether partial nephrectomy is feasible. A transverse abdominal incision is utilized for abdominal exploration and partial nephrectomy utilizing the same principles of radical nephrectomy with respect to tumor spillage. Manual compression of the kidney may control blood loss and avoid vascular ischemia. Tumor resection is accomplished by opening Gerota fascia and mass excision via wedge resection with 0.5-to 1.0-cm margin of normal renal parenchyma. Enucleation may be considered for large centrally located lesions. The specimen should be examined closely for rhabdomyomatous changes and anaplasia and nephrectomy considered in patients with positive margins or high-risk histology.¹¹⁶ Renal functional outcomes after nephron-sparing surgery are assessed by serum creatinine level, glomerular filtration rate, hypertension, and proteinuria.¹⁰⁸ Improved surgical techniques and intraoperative ultrasound have vastly improved the safety and feasibility of nephron-sparing surgery in children at risk of postoperative renal failure.

Future Directions

Future studies will continue to focus on personalized treatment plans based on tumor biology and patient risk stratification. New COG protocols are currently in place with efforts to further improve curative outcomes while minimizing toxicity with refined stratification based on tumor-specific biologic properties. Next-generation exome sequencing has enhanced the capacity to identify disrupted molecular pathways in Wilms tumors, and there is extensive research on identifying their role in Wilms tumor development and pathogenesis.¹¹⁷ There are very few known genetic alterations in Wilms tumors that have been shown to drive tumorigenesis or progression. Examples of this are the discovery of new mutations in Wilms tumor genes involved in miRNA processing including SIX1 and SIX2.¹¹⁸ Mutations in this pathway may underlie high-risk Wilms tumors and serve as biomarkers and new therapeutic targets. Several researchers have found significant epigenetic alterations such as changes in DNA methylation or chromatin structure in Wilms tumors. Epigenetic changes at the imprinted region at chr11p15.5 that show an allele-specific pattern of methylation resulting in abnormal expression of IGF2. Targeting IGF2 is an active area of investigation in preclinical drug development.¹¹⁹ Circulating epigenetically modified DNA and miRNAs have been detected in the blood of patients with cancer, leading researches to investigate the utilization of tracking genetic mutations in the circulation as a mechanism of diagnosis, risk stratification, and tracking tumor burden in Wilms tumor.^{117,120} Other areas of intense research continue in the role of myeloablative chemotherapy and the role of autologous bone marrow transplantation in patients with relapsed Wilms tumors.

NON-WILMS RENAL TUMORS

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma (fetal renal hamartoma) is the most common renal neoplasm in neonates and infants younger than 3 months and is considered a separate clinical entity from Wilms tumor. In contrast to Wilms tumor, classic congenital mesoblastic nephroma is considered a benign solid tumor of infancy, occurring in a younger age group with an excellent overall prognosis. Almost all cases are diagnosed within the first 6 months of life, representing 5% of renal neoplasms in children.¹²¹ There

may be a slightly higher incidence in boys.¹²² Congenital mesoblastic nephroma has distinctive spindle cell histopathologic and clinical features that are generally considered benign and rarely metastasizes to other organs. Congenital mesoblastic nephroma is a mesenchymal tumor with three pathologic variants: classic congenital mesoblastic nephroma, a cellular subtype, and a mixed variant. Cellular congenital mesoblastic nephroma subtype is a more aggressive tumor and, though rare, is capable of recurrence and metastases.¹²³ The cellular subtype is similar in histology to infantile fibrosarcoma and may represent a visceral form of the disease while classic histology is similar to infantile fibromatosis.¹²⁴ The cellular variant of congenital mesoblastic nephroma has been found to have a translocation (t12;15) (p13;q25) that results in ETV6-NTRK3 fusion protein, a genetic alteration also found in congenital infantile fibrosarcoma.¹²⁵ Similar to congenital infantile fibrosarcoma, trisomy 11 is also found in the cellular subtype of congenital mesoblastic nephroma.¹²⁶ These chromosomal aberrations distinguish the cellular variant of congenital mesoblastic nephroma from the classic variant.

Neonates and infants with congenital mesoblastic nephroma present with a palpable abdominal mass that is indistinguishable from other solid abdominal masses on physical examination. Hematuria is often present along with vomiting and jaundice in rare cases.¹²⁷ Hypertension or hypercalcemia is rarely present. The most common diagnostic imaging studies utilized are ultrasound and CT scan detailing the presence of a unilateral solid mass with or without cystic components, necrosis, or calcifications. The mass can be detected on prenatal ultrasound and polyhydramnios may be found in up to 70% of patients.¹²⁸ The diagnostic workup precedes in much the same manner as Wilms tumor, and the lesions are often not discernible on physical examination or preoperative imaging. The standard treatment of congenital mesonephric nephroma is complete surgical resection with nephrectomy. Wide margins are recommended because these tumors can infiltrate surrounding renal parenchyma and perinephric tissues. Local recurrence, though rare, has been reported and is associated with the cellular variant.¹²⁷ Systemic chemotherapy is reserved for tumors that recur and in rare cases of metastases or unusually cellular histology.

Clear Cell Sarcoma

Clear cell sarcoma of the kidney is a rare renal neoplasm of childhood, distinct from Wilms tumor. There are approximately 20 new cases in the United States each year. The median age of diagnosis of clear cell sarcoma of the kidney is 36 months and the tumor is one of the “unfavorable histology” tumors studied by the National Wilms Tumor Study Group and the COG. There is a male predominance with male to female ratio of 2:1.¹²⁹ Clear cell sarcoma of the kidney has morphologic diversity and is composed of sarcomatous, nonepithelial cells.¹³⁰ The classic microscopic pattern of clear cell sarcoma of the kidney is cords of round or spindle-shaped cells with clear cytoplasm and frequent empty-appearing “Orphan Annie” nuclei. The cord cells are surrounded by variants of regularly spaced arborizing fibrovascular septa resulting in cord widths of between four and 10 cells.¹³⁰ The cellular septa are characteristic of clear cell sarcoma and aid in diagnosis. The cord cells range from ovoid to spindle-shaped and the septa range from thin “chicken-wire” capillaries to sheaths of fibroblast-like cells in a collagenous matrix.¹²⁹ Most tumors have the classic histologic pattern though almost all demonstrate a secondary variant pattern. There are eight variant patterns recognized: myxoid (50%), sclerosing (35%), cellular (26%), epithelioid (13%), palisading (11%), spindle cell (7%), storiform (4%), and anaplastic pattern (2.6%).¹²⁹ Necrosis is associated with poor prognosis and tumors without necrosis are more often stage 1 tumors with superior outcomes.¹²⁹

Patients with clear cell sarcoma of the kidney present with a large unilateral abdominal mass that is best visualized by abdominal ultrasound and CT scan. The tumors are typically well circumscribed and consist of a solid mass with cystic foci components. Necrosis and hemorrhage are common. There is gross extension into the renal vein in 5% of cases. The most common site of metastatic disease is ipsilateral renal hilar lymph nodes (29%), and bone metastases are the most common mode of relapse.¹²⁹ Radiographic skeletal survey and radionuclide bone scan are critical to determine whether there are bone metastases at diagnosis. Patients may also have lung, brain, or liver metastases and, therefore, should have chest and central nervous system (CNS) imaging prior to initiation of chemotherapy for accurate staging. The staging system is similar to Wilms tumor. There is a high rate of metastases and relapse in early-stage tumors, and intensive chemotherapy is utilized for all cases. The current COG treatment recommendations for patients with clear cell sarcoma of the kidney include radical resection of the primary tumor and involved regional lymph nodes, followed by adjuvant chemotherapy consisting of vincristine, actinomycin-D, doxorubicin, and abdominal radiotherapy (10 Gy) for all stages. Since the addition of doxorubicin to the treatment protocols of clear cell sarcoma of

the kidney, patients with stage 1 disease have 6-year overall survival of 97%, stage 2 and 3 patients have 6-year survival of 75% and 77%, respectively (compared to 30% for both stages prior to doxorubicin), and stage 4 patients have 6-year survival of 50%.¹²⁹ There is active study within the COG on the benefit of the addition of cyclophosphamide and etoposide to treatment plans of patients with clear cell sarcoma of the kidney.¹³¹ There is propensity for late relapse and patients are monitored with abdominal imaging, chest radiography, brain MRI, and bone scanning.

Rhabdoid Tumor of the Kidney

Rhabdoid tumor of the kidney is a rare and aggressive cancer in infancy, constituting 1.8% of renal neoplasms in children. The cell of origin is unknown and the tumor was originally classified as a rhabdomyosarcomatoid subtype of Wilms but is now recognized as a distinct histologic tumor type. Histologically, rhabdoid tumors are well demarcated from the surrounding kidney and composed of solid and monotonous appearance of sheets of large cells with abundant cytoplasm, cytoplasmic inclusions, and prominent nucleoli.¹³² Intense vimentin immunoreactivity is characteristic and these tumors may also stain for cytokeratin, desmin, and neurofilament. Rhabdoid tumors may have areas of necrosis and foci of sclerosis.¹³² Rhabdoid tumors may occur as separate CNS primary tumors and up to 15% of patients with rhabdoid tumor of the kidney develop CNS lesions.¹³³ The overall prognosis of patients with rhabdoid tumor of the kidney remains poor and age is an important prognostic factor.¹³⁴ Patients diagnosed with rhabdoid tumors at less than 1 year of age have extremely poor prognoses and are at high risk for CNS tumors, while patients older than 1 year at diagnosis have better outcomes. Low stage and female gender have also been reported as features that predict improved survival.¹³³ Because of the small number of patients with this disease and overall poor outcomes, few other prognostic indicators have been identified. Rhabdoid tumors are characterized by loss-of-function mutations of the tumor suppressor gene *hSNF5/INI1* located at chromosome 22q11, which encodes a chromatin-remodeling protein complex (SWI/SNF).¹³⁵ This chromosomal alteration is thought to be a characteristic genetic defect for rhabdoid tumors of all sites.¹³⁶ Both acquired and germ-line mutations have been observed.¹³⁷ Although the functional consequences are not yet known, mutations in *INI1* have been found to result in altered transcription of genes involved in growth and differentiation.

Patients with malignant rhabdoid tumor of the kidney present with a palpable abdominal mass and often have hematuria. The diagnostic workup proceeds with an abdominal CT scan showing a large heterogeneous solid mass with areas of necrosis, hemorrhage, or calcifications. The tumor typically involves the renal hilum. A chest radiograph or chest CT scan should be obtained to evaluate for lung metastases. Lung metastasis is present in 56% of patients with rhabdoid tumor of the kidney at diagnosis and is the most common site of metastatic spread.¹³³ Evaluation for CNS disease should also occur at diagnosis because of the frequency of CNS primaries and metastases in patients with rhabdoid tumors. Therapy begins with radical nephrectomy and complete surgical resection including involved regional lymph nodes with paracaval and paraaortic lymph node sampling. Meticulous sampling of any potentially involved lymph nodes is critical for accurate staging. Patients are staged according to NWTs staging system, and all patients receive intensified adjuvant chemotherapy and abdominal radiotherapy. Based on current COG protocols, children with stage 1 to 3 malignant rhabdoid tumor of the kidney are treated with cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide for 30 weeks (regimen UH-1). Stage 4 patients receive vincristine, doxorubicin, cyclophosphamide that is alternated with cyclophosphamide, carboplatin, etoposide, vincristine, and irinotecan for 30 weeks (regimen UH-2). All patients receive abdominal radiotherapy. The survival rate for children with rhabdoid tumor of the kidney is dismal, with overall survival rates below 25% and very few survivors of stage 4 disease. Despite aggressive multimodal therapy, children younger than 1 year with rhabdoid tumor of the kidney have a 4-year survival of 8.8% and children older than 2 years have 4-year survival of 41.1%. Because previous protocols have had minimal successes with improving relapse and survival in children with malignant rhabdoid tumors, current COG clinical trials are examining intensive chemotherapy regimens and experimental agents in this high-risk renal tumor.¹³⁴

Renal Cell Carcinoma

Renal cell carcinoma is rare in pediatric patients and comprises approximately 5% of all renal tumors in children and adolescents.⁴ The tumor is highly aggressive with frequent distant metastases. The median age of diagnosis of renal cell carcinoma in children is 9 to 10 years, and children who have previously received cytotoxic chemotherapy may have predisposition to developing this cancer.¹³⁸ Pediatric renal cell carcinoma differs from adult renal cell cancer with distinct clinical and biologic differences. The

microscopic pattern does not typically fit well within the standard adult subtypes. In general, histology is consistent with papillary adenocarcinoma, renal cell carcinoma not otherwise specified, and clear cell adenocarcinoma subtypes.¹³⁹ High nuclear grade and increased vimentin expression is found in higher-stage cases.¹⁴⁰ Patients with von Hippel–Lindau syndrome may present with bilateral renal cell carcinoma. Tuberous sclerosis, Birt–Hogg–Dube syndrome, and hereditary leiomyomatosis are other hereditary syndromes associated with renal cell carcinoma.⁵ It is routine to test for translocations of the Xp11.2 and 6p21 loci, nonrandom genetic alterations that are characteristic of renal cell carcinoma.¹⁴¹ Tumors with Xp11.2 translocations have papillary and clear cell features and are a separate entity in the World Health Organization classification of renal tumors.¹⁴² This translocation may be present in up to 70% of pediatric renal cell carcinoma and involves the fusion of the *TFE3* gene, a transcription factor belonging to the microphthalmia (MiTF) family.¹⁴³ The translocation involving 6p21 is the second most common translocation in pediatric renal cell carcinoma and results in the fusion of *TFEB*, also a member of the MiTF transcription factor family.¹⁴³

Patients may present with a large palpable abdominal mass. Abdominal pain, hematuria, weight loss, joint pain, and anorexia may also be present. Cross-sectional abdominal and pelvic imaging (CT scan or MRI) along with chest radiography and/or chest CT scan is critical to define the locoregional extent of the mass and to determine metastatic spread. Distant metastatic disease is present in up to 30% of pediatric patients at diagnosis, most commonly to lung (64%), liver (57%), and bone (42%).¹⁴³ Local lymph node involvement does not necessarily predict poor outcome in renal cell carcinoma in children.¹⁴⁴ Imaging may show a large nonenhancing renal mass with necrosis or hemorrhage. Calcifications are more common in children with renal cell carcinoma than Wilms tumor.¹⁴⁵ Compared to adults, children with renal cell carcinoma present with higher-stage and higher-grade disease.¹⁴³ Children with renal cell carcinoma are staged on the basis of the International Union Against Cancer (UICC)/American Joint Committee on Cancer (AJCC; TNM) system although some studies utilize the modified Robson staging classification system.^{141,146} The overall survival at 20 years for pediatric renal cell carcinoma is 54.9%.¹⁴⁷

If the mass is resectable at diagnosis, standard treatment is radical nephrectomy with lymph node sampling, followed by combination adjuvant chemotherapy, immunotherapy, and radiotherapy based on surgical pathology. The role of lymph node dissection for renal cell carcinoma has not been determined. Partial nephrectomy is reserved for patients at high risk of postoperative renal failure and multiple renal tumors, particularly patients with genetic syndrome-related disease. There are reports of successful partial nephrectomy for small, unilateral, low-stage tumors. The role of chemotherapy is unproven, as the administration of chemotherapy has not significantly improved survival outcomes. There is some evidence that immunotherapy (IL-2) may be beneficial in select cases of renal cell carcinoma.¹⁴⁸ The COG recently completed a clinical trial (2006 to 2014) examining outcomes of high-risk renal tumors with complete surgical resection, intensive chemotherapy regimens, and radiotherapy. The most common agents utilized are combinations of vincristine, actinomycin-D, doxorubicin, cyclophosphamide, irinotecan, etoposide, and carboplatin (<https://clinicaltrials.gov/show/NCT00335556>). This prospective study should yield critical results on the optimal management of adjuvant therapy for this tumor.

RHABDOMYOSARCOMA

Epidemiology and Genetic Risk

Rhabdomyosarcoma is the most common soft tissue sarcoma in children with an overall incidence of approximately 350 cases per year in the United States.¹⁴⁹ The median age of presentation is 7 years of age and the majority of patients are diagnosed prior to 10 years of age. There is a slight male predominance and a slightly higher incidence in African-American children.⁴ Rhabdomyosarcoma tumors are classified as embryonal, alveolar, or pleomorphic histologic subtypes. Embryonal rhabdomyosarcoma (68%) is the most frequent histologic type and occurs in children younger than 4 years.¹⁴⁹ Alveolar rhabdomyosarcoma (31%) and pleomorphic subtypes (1%) occur more commonly in older children. The overall incidence of rhabdomyosarcoma has not changed much in the last 30 years although there has been an increase in incidence of the alveolar subtype and in cases presenting with distant metastases.¹⁴⁹ The overall survival for rhabdomyosarcoma has increased from 25% to more than 80% in the last four decades. This is largely due to improvements in multimodal therapies including radical surgery, intensive combination chemotherapy, and radiotherapy. Patients with embryonal

subtype have the best overall survival. Patients with smaller size tumors and favorable anatomic sites also have significant survival advantage. Age relates independently to survival outcomes with infants (<1 year of age) and adolescents (>10 years of age) more likely to have poor outcome and unfavorable histologic features.¹⁵⁰

Rhabdomyosarcoma is often associated with congenital malformations, most commonly the CNS and genitourinary systems, with nearly an eightfold increase in CNS anomalies in children with rhabdomyosarcoma.¹⁵¹ At least 32% of children with rhabdomyosarcoma have at least one congenital anomaly and nearly half are considered major defects. The rate of genitourinary defects in rhabdomyosarcoma is similar to that seen in children with Wilms tumors. There are also several familial syndromes associated with rhabdomyosarcoma. Children in families with Li–Fraumeni syndrome are at risk of developing rhabdomyosarcoma along with cancers of the breast, bone, brain, lung, and adrenal gland.¹⁵² Rhabdomyosarcoma has been reported at an increased incidence in patients with neurofibromatosis type 1 and in patients with Beckwith–Wiedemann syndrome.^{153–155} Environmental factors have also been found to have a role in the development of rhabdomyosarcoma. Parental use of recreational drugs has been associated with an increased risk. Several studies have suggested that cocaine and marijuana use in parents may increase the risk of rhabdomyosarcoma in offspring.¹⁵⁶

Pathology and Biologic Features

Rhabdomyosarcoma is a heterogeneous group of tumors. The origin is thought to be embryonal mesenchyme that gives rise to striated skeletal muscle. Rhabdomyosarcoma can occur in any skeletal muscle group but most commonly affected sites are head and neck, trunk, and genitourinary track. The Intergroup Rhabdomyosarcoma Study Group (IRSG), now the Soft Tissue Sarcoma Committee of the COG, classifies patients with rhabdomyosarcoma into the International Classification of Rhabdomyosarcoma (ICR) that is predictive of outcome among patients with different histologic subtypes.¹⁵⁷ Embryonal rhabdomyosarcoma is a heterogeneous subtype with histologic features that range from primitive mesenchymal cells to highly differentiated muscle cells. The small round blue cells consist of nuclei that are generally small with a light chromatin pattern. The microscopic pattern is moderately cellular with loose myxoid stroma.¹⁵⁷ Embryonal rhabdomyosarcoma comprises up to 75% of rhabdomyosarcoma tumors and is considered an intermediate prognosis tumor in terms of outcomes. Alveolar rhabdomyosarcoma is associated with poor prognosis. The tumors consist of small round cells with coarse chromatin and anastomosing fibrovascular connective tissue septa forming an alveolar pattern that is similar to lung in appearance (Fig. 105-10).¹⁵⁷ Botryoid tumors have excellent prognosis and have similar histologic characteristics of embryonal tumors but grow into hollow spaces such as bladder or vagina, assuming a characteristic grapelike appearance. Spindle cell rhabdomyosarcoma is another subtype of embryonal rhabdomyosarcoma that occurs most commonly at paratesticular sites and generally has excellent prognosis. Pleomorphic rhabdomyosarcomas are extremely rare in children and more common in adults. Rhabdomyosarcoma is detected on immunohistochemistry by desmin, myoglobin/Myo-D, or muscle-specific actin staining.¹⁵⁸ Myogenic phenotype may also be determined by electron microscopy.¹⁵⁹

Figure 105-10. Microscopic image of typical lung-like appearance of an alveolar rhabdomyosarcoma. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1997, with permission.)

Recurrent chromosomal alterations have been identified in rhabdomyosarcoma, particularly in alveolar subtypes.¹⁶⁰ Consistent translocations between chromosome 2 and 13, $t(2:13)(q35;q14)$, have been identified and occur in up to 55% of alveolar rhabdomyosarcoma tumors. The translocation results

in fusion of the *PAX3* and *FKHR* genes, both transcription factors that function in muscular development. The resulting gain of function fusion gene is thought to alter cellular apoptosis, growth, and oncogenesis.¹⁶¹ Another *PAX* gene translocation, *t*(1;13) (p36;q14), results in fusion gene *PAX7-FKHR* and also occurs in alveolar tumors.¹⁶² These recurrent chromosomal alterations rarely occur in embryonal rhabdomyosarcoma. Nearly 80% of alveolar tumors have *PAX3-FKHR* or *PAX7-FKHR* fusions detectable by polymerase chain reaction (PCR) and may aid in diagnosis.

Embryonic rhabdomyosarcoma is associated with allelic loss at chromosome 11p15.5, a possible tumor suppression region.¹⁶³ The mechanism of loss appears to preferentially maintain the paternal allele and lose the maternal allele, suggesting genomic imprinting.¹⁶⁴ Other genetic abnormalities have been identified through comparative genomic hybridization with whole chromosome gains and losses in embryonal rhabdomyosarcoma.¹⁶⁵ Genomic amplifications have been detected in alveolar subtypes and in embryonal rhabdomyosarcoma with anaplasia.¹⁶⁵

Presentation and Diagnosis

Rhabdomyosarcoma can arise at any mesenchyme-containing site in the body. The presenting signs and symptoms depend on the site affected. Approximately 35% of all rhabdomyosarcoma tumors arise in the head and neck region and include parameningeal and nonparameningeal sites. Tumors in these areas may cause headache, facial and cervical swelling, nasal obstruction or discharge, recurrent otitis media, and cranial nerve palsies.¹⁶⁶ Tumors of the genitourinary track account for 25% of rhabdomyosarcoma and are most commonly located in the bladder and the prostate gland. Perineal and perianal lesions may also occur. Patients may present with a palpable abdominal or pelvis mass, hematuria, dysuria, or urinary retention. Botryoid tumors are common in the vagina and the cervix and may present with vaginal bleeding and inflammation. The friable grapelike mass may protrude from the vaginal orifice. Paratesticular rhabdomyosarcoma presents with a painless mass in the scrotum that is typically distinguishable from the testicle. Extremity rhabdomyosarcoma tumors may present as swelling and pain after a traumatic injury to the extremity involved. Chest wall, paraspinal, and abdominal wall rhabdomyosarcoma are considered trunk sites and often present with palpable masses or chest wall pain. Additional primary sites include retroperitoneum, abdomen, and pelvis. These lesions may present as a palpable abdominal mass or with abdominal pain. There is seldom mass effect such as rectal or bladder obstruction. Biliary rhabdomyosarcoma may cause jaundice, fever, and right upper quadrant abdominal pain.

The diagnostic workup for rhabdomyosarcoma includes a thorough history and physical examination, followed by cross-sectional imaging of the involved site by CT scan or MRI. Local, regional, and distal metastatic extent of disease should be determined with assessment for abnormal appearing lymph nodes. PET scan may aid in detection of disease for adequate staging.¹⁶⁷ Complete blood count, serum chemistries, and liver function tests are routinely evaluated. Patients with suspected rhabdomyosarcoma should have bone marrow biopsies and aspirates performed to determine metastatic spread to bone marrow. Chest CT scan or chest radiograph is required to identify lung metastases. Bone scintigraphy should be obtained to search for cortical bone metastases. For most cases, brain CT scan and cerebral spinal fluid testing are reserved for patients with known CNS lesions or symptoms. An adequate biopsy is required to histologically confirm diagnosis. If the lesion is small or judged resectable on presentation, excisional biopsy with clear microscopic margins should be performed. If the tumor involves contiguous organs, major blood vessels, or nerves then incisional biopsy is performed. It is critical that the specimen is sent fresh to the pathologist without formalin and that enough tissue is obtained for microscopic evaluation and cytogenetic analysis.

Table 105-6 TNM Pretreatment Staging System

Stage	Site	T	Size	N	M
I	Orbit, Head and neck (excluding parameningeal), genitourinary (nonbladder/prostate)	T1 or T2	a or b	N0, N1, or N2	M0
II	Bladder/prostate, extremity, head and neck (parameningeal), other (trunk, retroperitoneum)	T1 or T2	a	N0 or Nx	M0
III	Bladder/prostate, extremity, head and neck (parameningeal), other (trunk, retroperitoneum)	T1 or T2	a b	N1 N0, N1, or Nx	M0
IV	All	T1 or T2	a or b	N0 or N1	M1

Reprinted from Lawrence W Jr, Anderson JR, Gehan EA, et al. Pretreatment TNM staging of childhood rhabdomyosarcoma: a report of the Intergroup Rhabdomyosarcoma Study Group. Children’s Cancer Study Group. Pediatric Oncology Group. *Cancer* 1997;80(6):1165–1170.

Staging

The most widely utilized staging system for rhabdomyosarcoma is based on the tumor, node, and metastases (TNM) staging system. TNM staging system is applied prior to treatment and assesses disease site of origin, tumor size, nodal status, and metastases as factors in prognosis (Table 105-6). This system was prospectively tested in IRSG clinical trials IRS-III and IV and reflects the biology of the tumor.¹⁶⁸ Most tumors are larger than 5 cm in size and 20% present with distant metastases at diagnosis (stage 4). Stage 1 tumors involve the head and neck, genitourinary (nonbladder/prostate), and biliary tract sites. Regional nodes may or may not be involved with stage 1 tumors. Stage 2 tumors involve the bladder/prostate gland, extremity, and cranial, parameningeal, retroperitoneal, and trunk sites and are smaller than 5 cm without lymph node involvement. Stage 3 tumors are the same anatomic sites as stage 2 and are larger than 5 cm with or without lymph node involvement. Any rhabdomyosarcoma tumor with distant metastases is considered stage 4 disease.

Clinical Group Assessment and Risk Status

Both stage and group assessment is used to assign risk categories and to determine treatment plan. The IRSG developed a surgical–pathologic clinical grouping system to standardize risk assessment in the IRS I and II therapeutic clinical trials. Patients are grouped into four risk groups on the basis of postoperative assessment of disease before initiating chemotherapy or radiation (Table 105-7).¹⁶⁹ Clinical group accurately predicts outcomes in patients with rhabdomyosarcoma.¹⁶⁹ Group I patients have excellent prognosis with localized tumors that are completely excised while group II patients have tumors that have microscopic residual disease or regionally invasive disease involving lymph nodes. Group III patients have gross residual disease or incisional biopsy, and group IV patients have distant metastases at presentation. Stage, clinical group, histology, age, and anatomic site are utilized to identify low, intermediate, and high-risk categories, and therapy is allocated on the basis of patient risk status. Favorable sites are orbit, head and neck (except parameningeal), genitourinary (except bladder and prostate), and biliary tract sites. Unfavorable sites are bladder/prostate, extremity, parameningeal, trunk, retroperitoneal, pelvis, and all other sites. Combinations of chemotherapy and radiotherapy are administered on the basis of risk group assignment. Alveolar and embryonal histology subgroups contrast in prognostic factors and in survival outcomes.

In patients with nonmetastatic rhabdomyosarcoma, tumors considered low-risk are embryonic rhabdomyosarcoma tumors (stage 1 or 2) located at favorable histology sites.¹⁷⁰ Embryonal tumors at unfavorable sites may also be assigned as low-risk group if the tumor is grossly completely resected (group 1 or II). There are two subsets of low-risk patient groups. Subset A (stage 1, group 1 or IIa; stage 2, group 1, group III orbit) is associated with worse failure-free survival (82%) in patients older than 10 years, though overall survival is the same as in younger patients (92%). This suggests excellent salvage therapy in this subgroup of patients. Low-risk subset B patients (stage 1, group IIb or IIc, stage 1, group III nonorbit; stage 2, group II, stage I, group 1 or II) with tumors larger than 5 cm also have worse failure-free survival (77%) but similar overall survival as patients with smaller tumors (93%).¹⁷⁰ The intermediate-risk embryonal rhabdomyosarcoma group comprises patients with unfavorable anatomic sites with tumor remaining after surgical excision. This risk group has worse survival outcomes than patients with low-risk tumors. In this group, patients with unresectable extremity rhabdomyosarcoma have extremely poor failure-free (43%) and overall (46%) survival.

Table 105-7 Surgical–Histopathologic Clinical Grouping System for the Intergroup Rhabdomyosarcoma Studies I and II

Group I: Localized tumor, completely resected
A. Confined to organ or muscle of origin
B. Infiltration outside organ or muscle of origin, regional nodes not involved
Group II: Compromised or regional resection including
A. Grossly resected tumors with “microscopic” residual
B. Regional disease, completely resected, in which nodes may be involved and/or tumor extends into an adjacent organ
C. Regional disease with involved nodes, grossly resected, evidence of microscopic residual
Group III: Incomplete resection or biopsy, gross residual disease
Group IV: Distant metastatic disease, present at presentation

Reprinted from Crist WM, Garnsey L, Beltangady MS, et al. Prognosis in children with rhabdomyosarcoma: a report of the Intergroup Rhabdomyosarcoma Studies I and II. Intergroup Rhabdomyosarcoma Committee. *J Clin Oncol* 1990;8(3):433–452, with permission.

In general, children with alveolar rhabdomyosarcoma have worse survival outcomes compared to those with embryonal histology. Patients with stage 1 or 2 tumor that is grossly resected (group 1 or 2) have 5-year failure-free survival of 80% and overall survival of 85%. Stage 1 or 2 (group III) patients have overall favorable outcomes as well. Children younger than 1 year with alveolar histology have considerably worse survival outcomes (43%). Patients with stage III tumors with nodal involvement also have poor survival outcomes (34%). Survival correlates with stage, and patients with high-risk tumors with distant metastases at diagnosis continue to have the worse expected survival of 25% despite intensified cytotoxic therapy and radiotherapy.

Treatment

Much of the treatment success of rhabdomyosarcoma is credited to successful clinical trials conducted by the IRSG and the Soft Tissue Sarcoma Committee of the COG. Multimodal therapy aims to minimize the risk of relapse and optimize curative outcomes, while also minimizing treatment toxicities. The INRG has completed five major clinical trials (IRS-I, II, III, IV, V/D) that provide the foundation upon which the current treatment schema is based for all children diagnosed with rhabdomyosarcoma. IRS-V or the “D” studies further refined treatment protocols on the basis of prognostic factors and risk stratification.^{169–172}

7 The mainstay of therapy begins with surgery, either complete excision with adequate margins or incisional biopsy. The goal for surgical margins is at least 0.5 cm of normal tissue surrounding tumor. Margins should be marked and oriented to ensure that pathologists can accurately identify each microscopic margin. Contiguous structures, organs, major blood vessels, or nerves that would result in major disability should not be resected in the initial operation, rather an adequate biopsy should be obtained and chemotherapy given upfront. In contrast, lesions that are small and not invading surrounding structures may be completely resected prior to chemotherapy. Resection of rhabdomyosarcoma tumors with wide and completely clear microscopic margins is the most ideal initial procedure for all stages to obtain local tumor control. Pretreatment re-excision is recommended after the initial operation if there is gross residual tumor or microscopically involved margins prior to the administration of chemotherapy. This is critical for accurate staging and for optimal clinical group assignment. Debilitating or highly morbid operations are performed only after chemotherapy and radiation have been given in attempt to decrease tumor burden and minimize extent of resection.

Lymph node sampling is indicated for patients with lesions that involve the extremity (even if clinically negative) or for clinically positive lymph nodes for all other sites. Biopsies by open, core, or sentinel lymph node biopsy techniques are all acceptable on the basis of current COG guidelines. Staging ipsilateral retroperitoneal lymph node dissection is recommended for paratesticular rhabdomyosarcoma for all males older than 10 years and for those younger than 10 years with enlarged lymph nodes appearing on CT scan. In this group, staging ipsilateral retroperitoneal lymph node dissection is required for adequate staging and risk group assessment. A nerve-sparing ipsilateral retroperitoneal lymph node dissection is recommended. The boundaries of the dissection begin at the level of the renal veins surrounding the aorta and the vena cava, extending to the deep inguinal ring. The procedure may be performed laparoscopically or through an open abdominal incision. Patients with intermediate-risk tumors may benefit from radical debulking of clinically positive lymph nodes if feasible.

The addition of chemotherapy and radiotherapy to treatment protocols for rhabdomyosarcoma has

dramatically improved survival rates. Currently, all children diagnosed with rhabdomyosarcoma receive adjuvant chemotherapy with or without radiotherapy. Current treatment protocols for patients with low-risk rhabdomyosarcoma (subgroups A and B) consist of vincristine, actinomycin-D, cyclophosphamide, and local radiotherapy to sites of residual disease (groups II and III). A recent clinical trial from the Soft Tissue Sarcoma Committee of COG (D9602) focused on eliminating cyclophosphamide and reducing radiotherapy doses in patients with lowest risk rhabdomyosarcoma.¹⁷³ This study found that the 5-year failure-free and overall survivals were lower than similar IRS-IV patients receiving cyclophosphamide. Given these results, the COG is currently studying a more modest dose reduction of cyclophosphamide (ARST0331, closed 2012) for both low-risk subgroups with aims of maintaining the excellent outcomes of IRS-IV and further reducing toxicity.¹⁷²

Intermediate-risk tumors are nonmetastatic and include alveolar rhabdomyosarcoma at any site (stages 1 to 3). Embryonal rhabdomyosarcoma in an unfavorable site that is incompletely excised (stage 2, 3, and group III) is also considered intermediate-risk. The standard chemotherapy for this group is vincristine, actinomycin-D, and cyclophosphamide with radiotherapy. Improvements in survival have not progressed as much in this group compared to low-risk tumors. IRS-IV did not show improvement in outcomes for intermediate-risk group patients by the addition of ifosfamide and ifosfamide/etoposide substituting for actinomycin-D and cyclophosphamide.¹⁷⁴ The COG recent intermediate-risk study (D9803) compared standard vincristine, actinomycin-D, and cyclophosphamide to a regimen that alternated standard therapy with vincristine, topotecan, and cyclophosphamide.¹⁷⁵ This regimen did not significantly improve outcomes compared to standard therapy. Results are pending from the COG's most recent trial (ARST0531, closed 2013) that randomized patients to receive standard therapy versus standard therapy alternating with vincristine and irinotecan, and earlier onset radiotherapy.¹⁷² The actions of vincristine and irinotecan are thought to be synergistic with enhanced cytotoxic activity based on preclinical and pilot studies.

High-risk patients have metastatic disease on presentation with dismal outcomes despite intensive cytotoxic therapy. Current therapy for high-risk tumors is based on results of the COG high-risk rhabdomyosarcoma phase II window studies (D9802) and previous IRS-I-IV trials.¹⁷⁶ These studies were the backbone for ARST0431 (closed 2010), which treated patients with multiple combinations of intensive chemotherapy that included vincristine, actinomycin-D, doxorubicin, irinotecan, cyclophosphamide, and ifosfamide/etoposide.¹⁷⁷ The feasibility of concurrent early administration of radiotherapy and irinotecan is also being evaluated. Long-term follow-up on the most optimal combinations of intensified chemotherapy in high-risk patients with rhabdomyosarcoma is needed. Recently, the COG study (ARST08P1) examined novel biologic agents. Cixutumumab, a monoclonal antibody against insulin-like growth factor-I receptor (IGF-IR), and temozolomide were added to intensive chemotherapy backbone regimens. Early results are promising for improved failure-free survival with cixutumumab but overall survival remains poor.¹⁷⁸

Radiotherapy in the form of external-beam radiation is utilized in group II to IV patients and in group 1 alveolar cases to enhance local control.¹⁷⁹ Radiotherapy is utilized as the primary means of local control in rare cases in which surgical excision carries excessive risk or concern for disfigurement (orbital and vaginal). Parameningeal tumors are treated with radiotherapy because of the high likelihood of residual disease with surgical excision. The most commonly utilized doses range from 36 Gy to 50 Gy, and higher doses are administered to patients with group III or IV disease (50 Gy given in 28 fractions).¹⁷⁹ The IRSG studied a trial of hyperfractionated radiotherapy versus conventionally fractionated radiotherapy in patients with group III rhabdomyosarcoma and found no differences in failure rates or survival outcomes.¹⁸⁰

Future Directions

Future clinical trials are focused on further tailoring therapies to reduce treatment toxicities and late adverse effects while improving curative outcomes. The current focus is incorporation of novel biologic agents to known active backbone chemotherapy regimens, particularly for patients with intermediate-risk and high-risk rhabdomyosarcoma. Human patient tumor-derived xenograft models are guiding future development of novel targeted therapies for this cancer. The National Cancer Institute supports the Pediatric Preclinical Testing Consortium, a program to evaluate novel molecules for genomically characterized solid tumors, including rhabdomyosarcoma (http://ctep.cancer.gov/MajorInitiatives/Pediatric_Preclinical_Testing_Program.htm).

NONRHABDOMYOSARCOMA SOFT TISSUE SARCOMA

Epidemiology

Soft tissue sarcomas in children and adolescents occur in approximately 8% of all childhood solid tumors. Nonrhabdomyosarcoma soft tissue sarcoma (NRSTS) represents approximately half of these cases, occurring in 250 to 300 children per year in the United States.¹⁸¹ Infants and adolescents are more commonly affected, and there is a slightly higher incidence in males and in African Americans. NRSTS comprises 27% of sarcomas in infants (<12 months), of which, 24% are fibrosarcomas, 1.7% are malignant fibrous histiocytoma (MFH), and 1.3% are peripheral nerve sheath tumors.¹⁸² The incidence of NRSTS has not changed in the last several decades. The overall 10-year survival has also remained steady at 73%. The tumors are distinct from rhabdomyosarcoma in terms of clinical characteristics, tumor biology, and prognosis. Most cases are sporadic although patients with Li–Fraumeni syndrome, neurofibromatosis type I (peripheral nerve sheath tumors), Gorlin syndrome (fibrosarcoma and leiomyosarcoma), and hereditary retinoblastoma have a higher risk of developing soft tissue sarcomas.^{183–185} Children who are survivors of childhood cancer are at an increased risk for NRSTS, particularly those with history of receiving radiation, high-dose anthracyclines, and alkylating agents.¹⁸⁶

Pathology and Biologic Features

NRSTS originates from developmental mesenchymal cells with heterogeneous histologic subtypes and diverse sites of origin. These tumors are classified on the basis of histology-specific cytogenetics of the tumor. NRSTS may have segmental chromosomal alterations (balanced translocations) or widespread genomic instability (Table 105-8). Most of the translocations found in NRSTS generate fusion proteins from two different transcription factors that disrupt normal embryonic development and drive sarcomagenesis.¹⁸⁷ ETV6-NTRK3 found in infantile fibrosarcoma and *anaplastic lymphoma kinase* (ALK) found in inflammatory myofibroblastic tumors are tumor cell-specific activated kinases that may have important roles in pathogenesis.¹⁸⁸ Dermatofibrosarcoma protuberans contain the *COL1A1-PDGFB* fusion gene.¹⁸⁹ Genetic analysis is a powerful tool for the diagnosis of NRSTS and is an important component of the histopathologic assessment. Detection of tumor-specific chromosomal alterations by RT-PCR, FISH, or high-throughput sequencing analyses often aids in confirming the diagnosis and in treatment planning.

Table 105-8 Nonrhabdomyosarcoma Tumor Characteristics

Tumor	Incidence ^{a,b}	Normal Counterpart ^a	Cytogenetic Abnormality ^a	Genes ^a	Common Primary Sites
Fibrosarcoma	0.6	Fibroblasts	<i>t</i> (12;15)	<i>TEL</i> (<i>ETV6</i>), <i>NTRK3</i> (<i>TRKC</i>)	Lower extremity, upper extremity

Presentation, Diagnosis, and Staging

NRSTS typically presents as a painless slow-growing solid mass that may invade surrounding structures. Approximately 15% of patients present with metastatic disease at presentation, most commonly lungs.¹⁹⁰ Survival for patients presenting with metastatic disease remains poor (35%), and disease-free progression is only 15% despite aggressive multimodality therapy. In general, diagnostic workup for NRSTS consists of cross-sectional imaging (MRI) of the primary site along with imaging (CT scan) of chest, abdomen, and pelvis for surgical planning and adequate staging. Bone scintigraphy is used only for patients with bone pain or symptoms. Bone marrow biopsy is typically not indicated. Brain imaging is reserved for patients with CNS symptoms.

An adequate tissue specimen is required to determine the histologic subtype and grade of NRSTS. Complete surgical resection of all gross diseases is recommended at presentation unless a wide resection is not feasible or accompanied by high surgical morbidity. Multiple core needle biopsies may be sufficient though the quality and quantity of specimen must be adequate for histologic and cytogenetic studies. Fine-needle biopsy is not acceptable for diagnosis. The fresh specimen should be evaluated for routine histopathology, immunohistochemistry, and molecular studies including DNA and RNA cytogenetic studies, flow cytometry, and electron microscopy.¹⁸⁶ Array technologies are being increasingly utilized in analysis of NRSTS, allowing measurements of tumor RNA expression and gene copy number.¹⁹¹ A pathologic tumor grade is assigned to NRSTS on the basis of extent of malignancy and is an indicator of prognosis. The grading system utilized in pediatric NRSTS was developed by the Pediatric Oncology Group using concepts of adult grading systems integrating characteristics of pediatric sarcomas.¹⁹² The Pediatric Oncology Group grading system for NRSTS assesses mitotic rate, extent of necrosis, differentiation, and histologic type and can be used as a predictor of outcome.

The size of the mass is important in initial surgical planning and determines surgical approach.¹⁹³ Tumor size of 5 cm is utilized by the American Joint Cancer Commission staging system of sarcoma as standard “cutoff” for resectability, though this has been difficult to translate to children with small body surface areas. This was addressed by the development of an equivalency factor that is utilized to calculate prognosis of soft tissue sarcoma based on size of the mass and body surface area.¹⁹⁴ Although tumor size is a key prognostic factor in adult soft tissue sarcomas, the risk is not the same in patients of different body sizes, and 5-cm cutoff may not pertain to infants and children.

Extent of disease, grade, size, and age, and extent of resection all influence prognosis and survival outcomes in NRSTS.¹⁹⁵ Patients are grouped into low, intermediate, and high-risk (metastatic disease) categories. High-risk patients have overall survival of approximately 15%, and most patients succumb to widespread metastatic disease. Intermediate-risk patients have unresectable tumors at presentation with residual disease or large (>5 cm), high-grade tumors. The survival in this risk group is approximately 50%. Low-risk tumors are completely resectable (<5 cm or equivalent) and are low grade.¹⁸⁶ Low-risk patients have the best prognosis with overall survival of 90%. In general, patients with negative microscopic margins have the best outcomes, and the addition of radiotherapy minimizes the risk of recurrence. A pediatric NRSTS staging system has not been validated. The IRSG surgicopathologic staging system for rhabdomyosarcoma is often utilized as well as the TNM sarcoma staging systems for adults. The COG is addressing the issue of staging for pediatric NRSTS in ongoing clinical studies.

Treatment

Complete surgical resection is critical in the management of NRSTS because of resistance to chemotherapy and radiotherapy. Primary tumors that appear grossly resectable should be excised upfront. If the surgeon anticipates that gross residual disease is likely following surgery or if complete excision is debilitating or disfiguring, tumor biopsy should be performed. This is typically seen with large (>5 cm), high-grade regionally invasive or metastatic tumors that will benefit from neoadjuvant chemotherapy and delayed tumor resection. Tumor debulking is generally not recommended. Large, potentially morbid resections such as amputation and pelvic exenteration are performed only after neoadjuvant therapies. In general, incisions on the extremities should be placed longitudinally and incisions on the trunk are oriented in the axial plane. If the surgeon determines that the mass is not amenable to full excision upfront, a generous incisional biopsy is required. Primary re-excision of the primary tumor is recommended if there is gross residual resectable tumor after the initial resection with at least a 0.5-cm margin. Re-excision is also recommended if the margin status is unknown. Previous scars or needle tracts should be included en bloc with the specimen. Lymph node sampling is required for abnormal appearing lymph nodes on clinical examination or imaging. Several histologic subtypes of NRSTS also require lymph node evaluation for risk assessment and staging purposes, even in patients without enlarged lymph nodes. These include synovial cell sarcoma, epithelioid sarcoma, and clear-cell

sarcoma with up to 30% risk of lymph node metastases.¹⁹³ In these groups, patients without radiologic evidence of nodal metastases may benefit from sentinel lymph node mapping with technetium 99m and biopsy rather than traditional lymph node sampling, though results have been mixed.^{196,197}

The most active chemotherapeutic agents for NRSTS are doxorubicin and ifosfamide, though most NRSTSs are relatively chemoresistant. Current treatment strategies are based on protocols from the COG clinical trial ARST0332 that assigned NRSTS patients to treatment groups on the basis of risk. Low-risk patients (grossly resected, low grade, any size) receive surgical excision alone with or without radiotherapy, depending on margins status. Intermediate-risk and high-risk (metastatic disease) patients are treated with ifosfamide and dose-intensive doxorubicin and radiotherapy either before or after surgical excision. The outcomes of this trial are pending. Because of the limited efficacy of chemotherapy in NRSTS, novel targeted therapeutic approaches are warranted, especially for children with high-grade or relapsed tumors.^{186,195}

HEPATIC TUMORS

Hepatoblastoma

Epidemiology and Genetic Risk

Hepatoblastoma is the most common malignant liver tumor in children, occurring in 0.7 per million to 1 per million children younger than 15 years, yielding approximately 100 cases per year in the United States.⁴ The incidence of hepatoblastoma has increased roughly 4% in the last three decades in the United States.¹⁹⁸ Hepatoblastoma occurs most commonly in infants and children between the ages of 6 months and 3 years. A slight male predominance is reported and there does not appear to be significant differences in incidence among race. The median age at diagnosis is 18 months of age. Hepatoblastoma is the third most frequent abdominal tumor after neuroblastoma and Wilms tumor. Environmental risk factors have not been confirmed. Hepatoblastoma has been found in association with prematurity and low birth weight.¹⁹⁹ There is a strong association with very low-birth-weight neonates (<1,500 g) though the underlying mechanism is not yet unknown.¹⁹⁸

Several inherited syndromes are associated with hepatoblastoma. Patients with Beckwith–Wiedemann syndrome are at risk for developing hepatoblastoma and require routine screening.²⁰⁰ Most cases are due to defective imprinting on chromosome 11p15.²⁰¹ Hepatoblastoma may also occur in children with hemihypertrophy and trisomy 18.²⁰² There is an increased risk of hepatoblastoma in children of families with familial adenomatous polyposis (FAP) syndrome though no specific genetic alteration in chromosome 5 has been identified.²⁰³ There is a nonrandom association between hepatoblastoma and children with trisomy 18.²⁰⁴

Sporadic hepatoblastoma has not been characterized by any single chromosomal abnormality and cytogenetic analyses have not revealed consistent patterns. The most common genetic abnormalities are trisomies.^{2,8,19,205} These genetic alterations are thought to have a role in hepatoblastoma pathogenesis, but the precise molecular mechanism is not understood. LOH of 11p15 has been detected in up to 33% of children with hepatoblastoma, and it is hypothesized that a tumor suppressor gene may be located in this region.²⁰⁶ Insulin-like growth factor 2 (IGF-2), a fetal mitogen, is an imprinted gene on 11p15 affected by β -catenin mutations.²⁰⁷ LOH at 11p is most often of maternal origin and commonly found in patients with Beckwith–Wiedemann syndrome. LOH has also been found at chromosome 1p and 1q and may have a role in tumorigenesis.²⁰⁸ Translocations involving the *NOTCH2* gene at chromosome 1 have been detected in hepatoblastoma tumors.²⁰⁹

Pathology and Biologic Features

Hepatoblastoma displays a combination of histologic patterns that range from epithelial and mesenchymal elements. This tumor is thought to originate from undifferentiated embryonal hepatic cells that maintain pluripotency and have potential to develop into both hepatocytes and biliary epithelial cells.^{210,211} Hepatoblastoma may be classified by five different histologic subtypes that carry prognostic value: well-differentiated fetal (pure fetal), embryonal, macrotrabecular (epithelial fetal or embryonal), small cell undifferentiated, and cholangioblastic (bile ducts predominate) (Table 105-9).^{212,213} Of these, the most favorable outcomes are seen with well-differentiated fetal subtypes. Small cell undifferentiated tumors (anaplastic subtype) carry the worse prognosis.²¹⁴ Small cell undifferentiated tumors are often associated with low or normal serum α -fetoprotein (AFP) levels

(<100) and predict adverse outcomes with poor response to chemotherapy.²¹⁵ The majority of hepatoblastoma tumors are epithelial with mixed embryonal and fetal patterns (67%), and 21% of these have mesenchymal components.^{213,216} Hepatoblastoma tumors secrete interleukin 1 β that induces IL-6 production, enhancing hepatocyte growth factor.²¹⁷ There is evidence that hepatocyte growth factor is secreted postoperatively and functions as a growth factor for hepatoblastoma tumor cells.²¹⁸

Presentation, Diagnosis, and Staging

Children with hepatoblastoma present with an asymptomatic abdominal mass or abdominal swelling. Systemic symptoms such as weight loss, failure to thrive, or anorexia may indicate advanced disease. Jaundice and biliary obstruction does not typically occur in patients with hepatoblastoma. Distant metastases are present in approximately 20% of patients at diagnosis and the most common site is lungs.²¹⁹ Ultrasound and cross-sectional imaging (three-phase CT scan or MRI with EOVIST) will define segmental extension of the tumor within the liver and assess for distant metastases (Fig. 105-11). The majority of hepatoblastoma tumors are located in the right lobe of the liver (up to 70%). The tumor appears as a solid mass with low attenuation. On MRI, the lesion appears as low intensity on T₁-weighted images and high intensity on T₂-weighted images. There is no evidence that MRI is superior to CT scan for diagnosis or surveillance of hepatoblastoma. It is important to distinguish central venous structures and to evaluate the liver for multifocal disease. Chest CT scan is obtained to evaluate for lung metastases. Anemia and thrombocytosis are common in children with hepatoblastoma and are likely related to cytokine secretion by tumor cells. AFP is elevated in approximately 90% of patients with hepatoblastoma and is a useful clinical marker for monitoring tumor responsiveness and recurrence. Interpretation of AFP may be difficult because the protein is expressed in the fetus and commonly remains elevated in normal neonates and infants up to 6 months of age. AFP may also be elevated in patients with hepatitis, hepatocellular carcinoma (HCC), and germ cell tumors. A high serum cholesterol level is also detected in 50% to 60% of children with hepatoblastoma.

Table 105-9 Relative Risk of Death for Histologic Subtypes of Hepatoblastoma^a

Histopathologic Subtype	Relative Risk of Death
Fetal	1.07
Embryonal	1.74
Mixed	0.53
Macrotrabecular pattern	1.20
Small cell undifferentiated	3.71

^aAdjusted for age, sex, and stage compared with other histologic subtypes.

Figure 105-11. Abdominal CT scan with right hepatic lobe hepatoblastoma displacing normal hepatic vasculature and parenchyma.

Staging is based on the COG hepatoblastoma staging system (Table 105-10). This system is a postsurgical staging system that is based on outcome of the primary operation before the administration of chemotherapy.²²⁰ Stage I (22%) is complete resection with clear margins. Stage II (0.5%) is complete gross resection with microscopic residual disease at the margins. Stage III (53%) is grossly positive

margins, biopsy only at diagnosis, nodal involvement, or tumor spill. Stage IV disease (23%) is metastatic tumor at diagnosis.²²¹

Table 105-10 Children’s Oncology Group Staging for Hepatoblastoma

Stage I	Complete resection
Favorable histology	Purely fetal histology with low mitotic index
Other histology	All other stage I tumors
Stage II	Gross total resection with microscopic margins or total resection with preoperative or intraoperative rupture
Stage III	Unresectable tumors as determined by the attending surgeon, partially resected tumors with microscopic margins, or any tumor with lymph node involvement
Stage IV	Measurable metastatic disease to lungs or other organs

Figure 105-12. The Liver Tumor Study Group of the International Society of Pediatric Oncology (SIOP) SIOPEL-1 pretreatment extent of disease grouping system, PRETEXT groups I–IV. L, left; R, right. (From Schnater JM, Aronson DC, Plaschkes J, et al. Surgical view of the treatment of patients with hepatoblastoma: results from the first prospective trial of the International Society of Pediatric Oncology Liver Tumor Study Group (SIOPEL-1). *Cancer* 2002;94(4):1111–1120, with permission.)

PRETEXT (pretreatment extent of disease) grouping is used internationally in combination with COG stage to stratify patients on the basis of the tumor’s radiographic characteristics prior to treatment.²²² PRETEXT describes the anatomic involvement and Couinaud hepatic segments affected by the tumor and can be applied to patients who have not yet had operations (Fig. 105-12).²²³ PRETEXT divides the liver into four parts termed sectors. The left lobe is divided into a lateral sector (segments 2 and 3) and a medial sector (segment 4). The right lobe is divided into an anterior sector (segments 5 and 8) and a posterior sector (segments 6 and 7). PRETEXT is further annotated by V (venous involvement), P (portal vascular involvement), E (extrahepatic involvement), M (distant metastatic disease), C (caudate lobe), F (multifocal), and R (rupture prior to diagnosis) categories. Imaging is obtained after every two cycles of chemotherapy, where POST-TEXT (posttreatment of disease) is then used to reassess anatomy.

The COG utilizes COG stage, PRETEXT, histology, and AFP at diagnosis to determine risk for therapy assignment and for clinical trial standards. In general, excellent prognosis is expected for stage I tumors completely resected at diagnosis with pure fetal histology. Poor prognosis is associated with PRETEXT

IV, metastatic tumors, AFP less than 100, and tumors with small cell undifferentiated histology.²¹⁶

Treatment

8 Complete surgical resection is the mainstay of curative therapy for hepatoblastoma. Completely resected tumors have significantly improved survival outcomes compared with all other hepatoblastoma patients. The tumor may present as large bulky disease with mass effect on surrounding abdominal structures. The umbilical fissure is typically not involved. If the tumor appears resectable, conventional resection is performed. If the mass is judged unresectable at diagnosis, incisional biopsy is performed and the patient is treated with chemotherapy prior to conventional resection. A complete preoperative evaluation is necessary to assess full extent of disease, PRETEXT grouping, and to determine a safe surgical plan that will achieve the highest survival outcomes. In the United States, tumor resection at diagnosis whenever possible is the preferred standard. This is based on the notion that a subset of patients may be spared toxicity of unnecessary neoadjuvant chemotherapy and that tumors have capacity to become resistant to prolonged chemotherapy.^{220,224} The COG currently determines surgical resectability based on PRETEXT grouping. Primary resection is recommended for localized PRETEXT 1 or PRETEXT 2 tumors with >1-cm radiographic margin on the middle hepatic vein, without vena cava or contralateral portal venous invasion.²²⁰ Neoadjuvant chemotherapy is recommended for PRETEXT III or IV tumors and for multicentric tumors with central venous invasion. Patients with pulmonary metastases also receive chemotherapy upfront. Tumor volume and AFP measurements may be utilized to monitor tumor responsiveness after each cycle. Minimal benefit may be seen by prolonging induction therapy after cycle 2; therefore, tailoring exposure to response may help reduce toxic effects.²²⁵

Conventional liver resection is safe and effective in children with hepatoblastoma, and surgical techniques have been optimized in the last three decades.^{226,227} An anatomic resection is recommended and is most often required. As much as 85% of hepatic parenchyma may be safely removed in children with full regeneration expected despite postoperative chemotherapy.²²⁸ Mortality from liver resection in children should be low (0% to 3%) with technical advances such as the Cavitron Ultrasonic Surgical Aspirator (CUSA; Cooper Lasersonics, Santa Clara, CA) and metallic clip applicators for hemostasis while dividing liver parenchyma. The surgical principles include a generous incision with wide exposure using bilateral subcostal incision. Dissection of the hilum with identification and isolation of the ductal and vascular structures of the segment of resection is critical. Hepatic arterial and portal venous inflow is obstructed or ligated, allowing demarcation of the resection plane. This allows the operation to proceed with minimal blood loss. Intraoperative Doppler ultrasound is often utilized to aid in locating major venous structures traversing the tumor and for ensuring adequate resection margins of at least 1 cm.

Chemotherapy improves resectability of hepatoblastoma and improves prognosis in nearly all cases. Currently most patients diagnosed with hepatoblastoma receive chemotherapy either before or after resection of the primary tumor. Based on results from the Pediatric Oncology Group/Children's Cancer Study Group studies INT-0098 and P9645, patients with completely resected well-differentiated fetal histology (WDF or pure fetal histology) tumors and low mitotic activity may be treated exclusively with surgery alone.²²⁹ Children with WDF histology tumors comprise 7% of hepatoblastoma cases and have 100% event-free survival. Most hepatoblastoma tumors are sensitive to cisplatin-based chemotherapy and overall survival increased from 30% to 70% with the addition of cisplatin.²³⁰ The COG currently recommends cisplatin, 5-fluorouracil, and vincristine for all low-risk tumors (non-well differentiated fetal histologic subtypes). Low-risk patients are patients with completely grossly resected tumors (stages I and II, PRETEXT I or II) without any small cell undifferentiated histology elements and who do not have a low diagnostic AFP (<100). This group can expect 5-year event-free survival and overall survival of 84% and 96%, respectively.²¹⁶ Intermediate-risk patients (PRETEXT II, III, or IV) are patients with gross residual disease or grossly resected disease with small cell undifferentiated histology (without metastases) and without low diagnostic AFP (<100). Those with high-risk tumors are any patients with metastatic disease and low diagnostic AFP level of <100. Patients with intermediate-risk and high-risk tumors are currently treated with cisplatin, 5-fluorouracil, vincristine, and doxorubicin. The COG is currently determining the efficacy of the addition of doxorubicin to intermediate and high-risk patients and for patients with minimal radiographic response to standard therapy. Depending on risk group protocol, patients will receive two to six cycles of cisplatin, 5-fluorouracil, vincristine with or without doxorubicin prior to primary resection or transplantation. Outcomes for patients with hepatoblastoma after surgical resection and chemotherapy were documented in INT-0098 with 5-year

event-free survivals for stages I, II, III, and IV of 91%, 100%, 64%, and 25%, respectively.²³⁰ Overall survivals were similar. The subsets of patients with stage III or IV disease who were able to have complete tumor resection and were tumor-free after induction chemotherapy had 5-year event-free survival of 83%. The role of radiotherapy in hepatoblastoma has not been defined because of the risk of hepatic toxicity and low hepatic tolerance to radiation in children. There may be a role for focal radiotherapy up to 45 Gy in patients with incomplete resection or microscopic residual disease.²³¹

Liver transplantation has become a promising treatment option for children with unresectable hepatoblastoma without metastatic disease after neoadjuvant chemotherapy.²³² Liver transplantation has improved overall survival in children with large or multifocal unresectable hepatoblastoma.^{233,234} Tumors with extensive major vessel involvement or multifocal disease should be referred to centers that have pediatric liver transplant expertise.²²⁰ Primary transplantation is also recommended for multifocal PRETEXT IV tumors despite apparent clearance after chemotherapy because of the risk of persistent microscopic disease.²³⁵ If after four cycles of chemotherapy, the tumor remains unresectable by conventional liver resection, liver transplantation is recommended. These are typically POSTTEXT IV or POSTTEXT III with major vascular involvement that would jeopardize blood supply to the contralateral lobe.²³⁶ A review of the United Network for Organ Sharing (UNOS) database revealed that overall 1-, 5-, and 10-year graft survival was 71%, 61%, and 58% for patients receiving liver transplant for hepatoblastoma. Overall 1-, 5-, and 10-year patient survival was 79%, 69%, and 66%.²³⁷ Other series have reported similar success.²³⁴ The primary cause of death was metastatic and relapsed disease. For transplantation eligibility, patients with hepatoblastoma must not have any active extrahepatic or metastatic sites that have not cleared with surgery or chemotherapy. Patients with lung metastases are not excluded from transplantation if the lung disease is clear after neoadjuvant chemotherapy. It is critical to correctly identify patients who will benefit from primary liver transplant prior to attempts at conventional resection because liver transplant after incomplete tumor resection or hepatic relapse has had disappointing results, with reported survival for “rescue” transplant of only 40%.²³⁸

The COG and other large international cooperative groups are investigating novel therapeutic strategies. COG AHEP-0731 is a COG study that is randomizing patients with metastatic disease to receive a novel upfront window design of vincristine, irinotecan, vincristine, irinotecan, and temsirolimus prior to standard cisplatin, 5-fluorouracil, vincristine, and doxorubicin therapy.²³⁹ Chemotherapeutic intensification by dosing and duration has had promising preliminary results and may be beneficial in patients with high-risk hepatoblastoma. The expanding roles of antibodies and T lymphocytes as anticancer therapy for pediatric solid tumors may also hold promise as novel treatment agents for hepatoblastoma.²⁴⁰

Hepatocellular Carcinoma

HCC occurs more commonly in older children and is similar in histopathology to the disease in adults. HCC accounts for less than 0.5% of pediatric tumors and is the second most common malignant liver mass in children after hepatoblastoma. Risk factors and preexisting liver diseases for HCC include cirrhosis, type 1 glycogen storage disease, autoimmune hepatitis, and primary sclerosing cholangitis.²²⁰ Areas endemic for hepatitis B have higher incidences of HCC in children. HCC is rare in infancy and there is a slight male predominance. HCC tumors are classified as either epithelial variant (75%) fibrolamellar (15%), and rarely poorly differentiated or clear cell.²⁴¹ Differences in outcome or treatment response among children with different histologic subtypes of HCC have not been confirmed. The fibrolamellar subtype is seen more often in younger children and rarely occurs with cirrhosis. The most common presenting symptom is hepatomegaly and abdominal pain although HCC is often indistinguishable from hepatoblastoma on physical examination, imaging, and laboratory values. The diagnostic workup mirrors hepatoblastoma and diagnosis is confirmed by histopathologic examination of tumor biopsy or resection. HCC is more likely to have multifocal nodules with intrahepatic venous and lymphatic spread. More than one-third of patients have lung metastases at diagnosis. The PRETEXT grouping system is utilized for risk assessment and to determine resectability. PRETEXT III and PRETEXT IV are the most common categories at presentation in patients with HCC.

As reported by the Intergroup Pediatric Oncology Group Study 8945/CCG 8881, 17% of patients diagnosed with HCC had stage 1 disease, none had stage 2 disease, 54% had stage 3 disease, and 28% had stage 4 disease.²²¹ It is not clear whether AFP levels can be used to predict outcome in HCC similarly to hepatoblastoma as study results have not been consistent.²²¹ The overall event-free survival for children with HCC at 5 years was 19%. Stage 1 disease had the best outcome compared to stage 3 and 4 diseases. The 5-year event-free survival for stage 1, 3, and 4 diseases was 88%, 8%, and 0%,

respectively.²²¹ Overall survival was similar to event-free survival for each disease stage. Complete surgical resection or transplantation has the highest potential for cure in children with HCC. Unfortunately, fewer than 20% of patients with HCC have tumors that are resectable at diagnosis and multifocal tumors are common. In contrast to hepatoblastoma, HCC tumors are generally unresponsive to chemotherapy and outcomes for patients with stage 3 disease and higher are dismal. Transplantation is reserved for patients with localized tumor without any evidence of metastatic disease at presentation because of high risk of pulmonary metastatic relapse.²²⁰ The guidelines for liver transplantation in HCC are largely derived from the adult experience using the Milan criteria (not more than three tumors, smaller than 3 cm in size, or single tumor smaller than 5 cm in size).²⁴² The COG studies on liver tumors and hepatoblastoma include children with HCC and treatment regimens have generally been the same. Treatment protocols for HCC currently consist of cisplatin, vincristine, doxorubicin, and 5-fluorouracil in multiple combinations. Compared to hepatoblastoma, these agents are not as effective in HCC, and patients generally remain with poor prognosis.²³⁰ The majority of patients do not undergo postinduction surgery or liver transplantation because of the presence of either unresectable or metastatic disease.

Alternative approaches for local control have demonstrated some benefit in children with HCC. Hepatic arterial chemoembolization in patients with refractory and unresectable disease requires cooperative group study but has been shown to be well-tolerated and may be effective in inducing surgical resectability in select cases of HCC.²⁴³

Chapter 106

The Pregnant Patient

Juan L. Martinez-Poyer and N. Scott Adzick

Key Points

- 1 One of the most significant advances in the reduction of morbidity of prematurity has been the use of antenatal corticosteroids.
 - 2 To accommodate the fetus, placenta, and amniotic fluid, the uterus increases in size and weight and its walls become thinner. By the end of the first trimester, the uterus moves out of the pelvis and by 20 weeks reaches the level of the umbilicus. By term, it almost reaches the liver.
 - 3 The etiology of preterm labor is often multifactorial, but the onset of labor from fetal and uterine stress from surgical manipulation is of most concern to the surgeon.
 - 4 Initiation of tocolytic therapy for potential but unconfirmed preterm labor is discouraged.
 - 5 Exposure to diagnostic levels of radiation carries little chance for spontaneous abortion, teratogenesis, or growth retardation. The increased risk of future cancer, however, does exist and must be weighted against the utility of information provided by the study.
 - 6 Attributing abdominal pain to other etiologies, failure to pursue further investigation, and the physicians' fear of surgically induced premature labor all contribute to delayed diagnosis, higher perforation rates, diffuse peritonitis, preterm labor, and fetal loss in pregnant patients with appendicitis.
 - 7 Cholecystectomy can be performed safely and effectively during pregnancy in all trimesters. Nonoperative management of symptomatic cholelithiasis is associated with significant recurrent bouts of symptoms, prolonged total parenteral nutrition, higher rates of preterm delivery, cesarean section, and more technically difficult cholecystectomies.
 - 8 Adhesions remain the most common cause of intestinal obstruction in the gravid patient, with 89% to 100% of patients eventually requiring an operation.
 - 9 Pregnant patients present with more advanced colorectal cancers than the population as a whole. The necessary treatment must balance oncology outcomes with effect on the pregnancy, and decisions regarding the management of pregnancy include termination, iatrogenic prematurity, or intentional delay in treatment.
-

The general surgeon at some point in his or her career will be asked to operate on an obstetrical patient or be urgently consulted for intraoperative assistance with an unanticipated surgical finding or complication. To provide the best support, it is imperative that he or she is knowledgeable of the normal physiologic variations occurring during pregnancy, the frequency and nature of presentation of surgical disease, the safety and utility of diagnostic imaging modalities, and the newest surgical techniques to ensure the safety and well-being of the mother and the fetus. To achieve this goal, the concerted effort and close working relationship between various specialties cannot be overemphasized.

This chapter reviews the current data on the presentation, frequency, and treatment of some common surgical diseases during gestation, as well as their impact on pregnancy.

FETAL DEVELOPMENT

1 Human development begins immediately on fertilization of the oocyte by the sperm, but because in many cases it is very difficult to determine the exact time of fertilization, pregnancy is generally dated from the first day of the last menstrual period. However, dating using menstrual age is less accurate than early ultrasonography dating because of reliance on recall, cycle length variability, and pregnancy after cessation of oral contraceptives or following childbirth.^{1,2} Ultrasonography provides a better estimate of the date of delivery than a reliable last menstrual period before 20 weeks of gestation, with

an optimum for examinations performed in the first trimester when crown–rump length is within 5 days of the date of conception in 95% of the cases.^{3–5} The embryonic period refers to the earliest stages of development and extends to the end of the eighth week, by which time organogenesis has occurred. The fetal period lasts from the ninth week to birth. During this period, growth and development of tissues formed during embryogenesis occur in preparation for birth. By the beginning of the third trimester, the fetus may survive if born prematurely.⁶ Survival outside the womb depends on the adaptation of fetal organ systems for independent function at the time of birth. The functional status of the respiratory system is crucial in determining fetal viability. Perivable birth is defined as birth from 20⁰/₇ weeks through 25⁶/₇ weeks. Infants born before 20 weeks are considered abortions. Infants born at 20 weeks and 21 weeks do not survive. The survival data for births at 22, 23, 24, and 25 weeks of gestation, excluding infants with birth weights lower than 401 g, greater than 1,000 g, and infants with major anomalies, are 6%, 26%, 55%, and 72%, respectively.⁷ Surfactant, a complex mixture of phospholipids consisting mostly of phosphatidylcholine, is necessary for reduction of surface tension at the alveolar–air interface and proper oxygen exchange. Surfactant production begins by the 20th week of gestation but is present in only small amounts before 24 weeks.⁶ One of the most significant advances in the reduction of morbidity of prematurity has been the use of antenatal corticosteroids. Binding of corticosteroids in the fetal lung not only increases secretion of phosphatidylcholine but also induces morphologic development of pulmonary epithelial cells and increases neonatal lung compliance. Corticosteroids stimulate development of other organ systems as well, decreasing the incidence of necrotizing enterocolitis, intraventricular hemorrhage, periventricular leukomalacia, and death. The maximum developmental effects can be seen as early as 24 hours after maternal administration of dexamethasone or betamethasone, and administration at the first sign of premature onset of labor can improve survival, particularly before birth between 22 and 25 weeks.^{8–10}

UTERINE ANATOMY AND PHYSIOLOGY OF LABOR

2 The uterus is a muscular organ responsible for reception, implantation, development, and expulsion of the fetus. In the nonpregnant woman, the uterus lies in the pelvis, weighs approximately 70 g, and has a cavity volume of 10 mL. To accommodate the fetus, placenta, and amniotic fluid, the uterus increases in size and weight and its walls become thinner. By the end of the first trimester, the uterus moves out of the pelvis and by 20 weeks reaches the level of the umbilicus. By term, its capacity is 500 to 1,000 times greater than that in the nonpregnant state. With progressive increase in size, the uterus contacts the anterior abdominal wall, displaces the bowel laterally and superiorly, and almost reaches the liver ([Fig. 106-1](#)).¹¹ Coupled with its ascent from the pelvis, the uterus usually rotates to the right due to the presence of the rectosigmoid on the left side of the pelvis. When the pregnant woman lies supine, the uterus rests on the vertebral column and compresses the abdominal great vessels, particularly the inferior vena cava. Right before the last weeks of pregnancy, the uterus undergoes sporadic, nonrhythmic and painless contractions that are known as Braxton Hicks contractions. The intensity of these contractions varies between 5 and 25 mm Hg. At term, these contractions become well-coordinated, reaching pressures up to 80 mm Hg. The factors responsible for the onset and maintenance of normal labor at term are not completely understood. Multiple mechanisms are responsible for the spontaneous contraction–relaxation cycles in human myometrium, including changes in intracellular calcium concentrations, alteration in membrane potential, phosphorylation and dephosphorylation of myosin light-chain kinase, activation of phosphatases, and recruitment of a number of intracellular signal pathways. During pregnancy, uterine contractility is maintained in a state of quiescence through the action of various inhibitors that include but are not limited to progesterone, prostacyclin, relaxin, parathyroid hormone–related peptide, nitric oxide, calcitonin gene-related peptide, adrenomedullin, and vasoactive intestinal peptide. Parturition begins as a consequence of release from the inhibitory effects of pregnancy on the myometrium as well as recruitment of uterine stimulants such as estrogen, oxytocin, and stimulatory prostaglandins (e.g., PGE₂, PGF₂α, IL-1, and IL-6). The final common pathway toward parturition appears to be maturation and activation of the fetal hypothalamic–pituitary–adrenal (HPA) axis. The result is a dramatic increase in production of the C19 steroid dehydroepiandrosterone sulfate. The cellular and molecular factors that are responsible for maturation of the fetal HPA axis seem to be associated with the gestational age-dependent upregulation of a number of critical genes within each component of the HPA axis: corticotropin-releasing hormone (CRH) from the fetal hypothalamus, proopiomelanocortin from the fetal pituitary, and

Adrenocorticotrophic hormone (ACTH) receptor and steroidogenic enzymes in the fetal adrenal gland. Animal models have shown that undernutrition of the mother around the time of conception leads to precocious activation of the fetal HPA and preterm birth. This suggests that, although maturation of the fetal HPA axis is developmentally regulated and the timing of parturition may be determined by a “placental clock” set shortly after implantation, stress may accelerate this clock. Levels of CRH in the maternal circulation increase from between 10 and 100 pg/mL in nonpregnant women to between 500 and 300 pg/mL in the third trimester of pregnancy and then decrease precipitously after delivery. The source of the excess CRH is the placenta. The production of CRH by the placenta is upregulated by corticosteroids produced primarily by the fetal adrenal glands at the end of pregnancy. Under the influence of estrogen, hepatic-derived CRH-binding protein concentrations also increase in pregnancy. Circulating CRH levels increase and CRH-binding protein levels decrease before the onset of both term and preterm labor, resulting in a marked increase in free, biologically active CRH. At a molecular level, CRH acts by binding to specific nuclear receptors and affecting transcription of target genes. A number of CRH receptor isoforms dominate, and CRH promotes myometrial quiescence by inhibiting the production and increasing the degradation of prostaglandins, increasing intracellular cyclic adenosine monophosphate, and stimulating nitric oxide synthetase activity. At term, CRH acts primarily through its low-affinity receptor isoforms, which promotes myometrial contractility by stimulating prostaglandin production from the decidua and fetal membranes and potentiating the contractile effects of oxytocin and prostaglandins on the myometrium.¹²

Figure 106-1. Enlarging uterus during gestation. At 12 weeks, the uterus rises out of the pelvis into the abdomen. At 20 weeks, the fundus is at the height of the umbilicus, and at 36 weeks, the uterus reaches to the upper abdomen.

PREMATURE ONSET OF LABOR

3 Preterm birth is defined as birth between 20⁰/₇ weeks and 36⁶/₇ weeks of gestation. The diagnosis is made clinically on the basis of the presence of regular uterine contractions accompanied by a change in cervical dilatation, effacement, or both, or initial presentation with regular contractions and cervical dilatation of at least 2 cm. Although only 12% of all live births in the United States fit this criterion, prematurity is responsible for approximately 70% of neonatal deaths, 36% of infant deaths, 25% to 50% of cases of long-term neurologic impairment in children, and a high cost to the health care system.^{13–17} Preterm labor with intact membranes is not the only cause of preterm birth; numerous preterm births are preceded by either rupture of membranes or medical/surgical problems necessitating delivery.^{18,19} The etiology of preterm labor is often multifactorial, but the onset of labor from fetal and uterine stress during surgical manipulation or intra-abdominal inflammatory processes is of most concern to the surgeon. Bacterial infection of the amniotic tissues or peritoneum leads to a local increase in eicosanoids and the onset of labor.²⁰ Endotoxin acts on inflammatory cells to increase production of IL-1 and IL-6, which also amplify local prostaglandin production. All of these factors can act in concert to initiate and propagate preterm labor. Uterine activation and increased expression of gap junctions as well as oxytocin receptors can be induced by uterine stretch.²¹ Uterine trauma due to surgical manipulation can affect these same mechanisms, leading to premature uterine contractions. The interrelations at various

levels between the inflammatory response, uterine and maternal trauma, and the initiation of labor can represent the body's attempt to expel the fetus from a hostile uterine environment.

Tocolysis

4 To date, there is no evidence that tocolytic therapy has associated direct benefit on improving neonatal outcome, except for short-term prolongation of pregnancy (up to 48 hours) to allow for the administration of antenatal steroids, transport of the patient to a tertiary care facility, and fetal neuroprotection.²²⁻²⁴ In general, tocolysis is indicated between viability (24 weeks of gestation) and 34 weeks of gestation in women with preterm contractions with cervical change. However, it is accepted to administer tocolytics before viability after events known to cause preterm labor, such as intra-abdominal surgery and in utero fetal surgery although evidence of efficacy for such intervention is lacking.^{25,26} Prostaglandin synthesis inhibitors, magnesium sulfate, beta₂-adrenergic agonists, and calcium channel blockers represent the four most common pharmacologic agents used as tocolytics. Because of the importance of prostaglandins in the initiation of uterine contraction, prostaglandin synthetase inhibitors are used to stop premature labor. Indomethacin is the nonsteroidal drug used most frequently for tocolysis because of its quick onset of action and ease of dosing. Studies report a 95% tocolytic success rate at 48 hours and a potential delay in delivery of 1 week in 80% of patients.²⁷ Magnesium sulfate has long been used in the treatment of preeclampsia and has gained acceptance as a tocolytic and more recently as a neuroprotective agent to reduce the risk and severity of cerebral palsy when birth is anticipated before 32 weeks of gestation. Most data support the theory that magnesium exerts its effects by calcium antagonism. High intracellular magnesium concentrations inhibit Ca²⁺ entry into myometrial cells, interfering with actin–myosin coupling. High magnesium concentrations also increase the sensitivity of K⁺ channels, favoring hyperpolarization and uterine relaxation. Maternal serum levels necessary to inhibit myometrial contractility range between 4 and 9 mg/dL, two to six times normal levels.²⁸ Beta₂-adrenergic agonists used in the treatment of preterm labor include ritodrine and terbutaline. Stimulation of uterine beta₂ receptors leads to activation of adenylate cyclase and an increase in intracellular cyclic adenosine monophosphate (cAMP) concentration. Activation of -dependent protein kinase A inhibits myosin light-chain phosphorylation and actin–myosin coupling. Protein kinase A activity is also associated with increased Ca²⁺ efflux, decreased Ca²⁺ influx, and increased K⁺ conductance. All these actions lead to myometrial relaxation. Because of reports of serious maternal side effects and possible adverse behavioral effects in offspring after in utero exposure to terbutaline, the U.S. Food and Drug Administration (FDA) issued a warning regarding the aforementioned agent and suggested that its use be limited to short-term inpatient acute tocolysis particularly in the setting of tachysystole.^{29,30} Calcium channel blockers inhibit entry of calcium through voltage-dependent Ca²⁺ channels. The use of oral nifedipine can abolish uterine activity and prevent delivery with minimal maternal side effects and no reported fetal or neonatal adverse effects.³¹ However, maternal and fetal side effects can be serious with other tocolytic agents. Premature constriction of the fetal ductus arteriosus and necrotizing enterocolitis with the use of indomethacin has been reported and can result in neonatal pulmonary hypertension and even death.^{32,33} Maternal cardiovascular side effects, including pulmonary edema, can occur in 5% of beta₂ agonist users and 10% of those treated with magnesium. Although this complication is rare, it can result in maternal death. Serum concentrations of magnesium needed for tocolysis (4 to 9 mg/dL) are not far from levels causing ablation of deep tendon reflexes (9 to 13 mg/dL) or respiratory depression (14 mg/dL). The decision to use tocolytics must be made only after the diagnosis of premature onset of labor is confirmed, and the benefits of prolonging gestation outweigh the risks of tocolysis. Initiation of tocolytic therapy for potential but unconfirmed preterm labor is discouraged.³⁴ Maintenance therapy with any of the aforementioned tocolytic agents has not been demonstrated to prolong pregnancy or improve neonatal outcomes after an initial treated episode of threatened preterm birth and, therefore, should not be used for this purpose.³⁵⁻³⁷

FETAL MONITORING

Perioperative fetal monitoring as well as the monitoring of premature uterine contractions is based on technology developed for intrapartum fetal monitoring in the late 1950s and early 1960s. Observational studies performed at that time and in the mid-1970s convincingly established a relationship between the degree of fetal acidemia and the presence and depth of decelerations and decreased or absent fetal heart

rate variability.^{38,39} Established heart rate patterns and variable cardiac responses to fetal and maternal stimuli reflect an intact, well oxygenated central nervous system (CNS). Identification of deviation from those patterns indicative of metabolic acidosis was hoped to decrease the incidence of hypoxic–ischemic encephalopathy and death. Meta-analysis of randomized controlled trials comparing electronic fetal monitoring with intermittent auscultation has failed to show that electronic fetal monitoring decreased neurologic morbidity and mortality.⁴⁰ Recently, researches using the US 2004-linked birth and infant death data found that the use of electronic fetal monitoring was associated with a substantial decrease in early neonatal morbidity particularly in preterm fetuses.⁴¹ However, authorities in the field remain skeptical of the findings and have cautioned that an epidemiologic association between fetal monitoring and reduced neonatal death does not establish causation.⁴² This controversy is not expected to be solved any time in the near future, but the fact is that of the approximately 4 million live births a year in the United States, 85% are assessed with fetal heart rate monitoring, making it the most common procedure in pregnancy.⁴³ Fetal heart rate monitoring may be performed externally or internally. Most external monitor devices use the Doppler principle with computerized logic to count and interpret the Doppler signals originating from the fetal heart and maternal uterus. Internal fetal heart rate monitoring is accomplished with a spiral device attached to the fetal scalp or other presenting part. A transcervical intrauterine pressure catheter is sometimes used to monitor more accurately the strength and frequency of uterine contractions (Fig. 106-2). Both tracings are printed on a continuous strip of paper, with the fetal heart rate plotted at the top of the graph and uterine activity at the bottom.

Fetal Heart Rate

Normal fetal heart rate during pregnancy ranges between 110 and 160 beats/min. A prolonged baseline above 160 beats/min is considered a tachycardia, whereas that below 110 beats/min is a bradycardia. These terms refer to long-term patterns, and minute-to-minute variability in the heart rate away from baseline is known as acceleration and deceleration. Normal fetal heart rate tracings express continuous adjustment in the vagal tone through variability in the heart rate. Short-term or beat-to-beat variability is superimposed on broader, long-term variability of the baseline by three to five beats/min. The fetal heart rate response governed by a nonacidotic, well-functioning vagal conduction system manifests both long-term and short-term variability, with fluctuations of peaks and troughs ranging from 6 to 25 beats/min (Fig. 106-3). Decreased heart rate variability, either long or short term, can signal diminished CNS activity. Although this can be a physiologic response of the fetal sleep–wake cycle or maternal medication and sedatives, persistently decreased reactivity can signal CNS acidosis. Fetal heart rate accelerations are normal findings in the second half of pregnancy and occur as a result of increased sympathetic stimulation and decreased parasympathetic stimulation with fetal movements. Fetal heart rate decelerations are usually encountered during uterine contractions of the intrapartum period. Evaluation of decelerations during labor and as part of intraoperative fetal monitoring can give clues to the status of the placental blood supply. A prolonged deceleration is a visually apparent decrease in the fetal heart rate baseline that is 15 minutes or more, lasting 2 minutes or more but less than 10 minutes in duration. Early decelerations are characterized by a symmetrical and gradual decrease and return of the fetal heart rate that mirror uterine contractions and reflect increased vagal tone from a transient increase in intracranial pressure. This pattern is considered a benign physiologic manifestation of a functioning autonomic nervous system and has no adverse outcome. Variable decelerations are distinctively recognized by their abrupt decrease in fetal heart rate of 15 beats/min or greater from the onset of the deceleration to the beginning of the fetal heart rate nadir of 30 seconds, lasting 15 seconds or greater, and less than 2 minutes in duration. When variable decelerations are associated with uterine contractions, their onset, depth, and duration vary with successive uterine contractions. Isolated variable decelerations have little clinical significance, but if persistent with inadequate recovery between contractions, fetal hypoxemia and acidosis can occur. Late decelerations present usually as a symmetrical and gradual decrease and return of the fetal heart rate associated with a uterine contraction. The deceleration is delayed in timing, with its nadir occurring after the peak of the contraction. Late decelerations have an ominous connotation as they usually represent significant uteroplacental compromise; causes can range from maternal hypotension due to inferior vena cava compression to hypoxia or anemia.⁴⁴ Intraoperative fetal compromise as indicated by an ominous heart rate tracing must be treated by correcting maternal hypotension or increasing oxygen delivery with increased FIO_2 , positional changes, aggressive fluid resuscitation, or blood transfusion. The inability to improve the intrauterine milieu can necessitate an emergent cesarean section to prevent fetal demise.⁴⁵ The decision to use continuous fetal heart rate monitoring during nonobstetric surgery in pregnancy is

controversial and should be based on gestational age, type, site, duration, and extent of the procedure. For previable pregnancies (<23 weeks), documentation of fetal heart activity by Doppler before and after the procedure suffices.⁴⁶ For viable gestations, there is less consensus for fetal heart rate monitoring, but at a minimum, simultaneous electronic fetal heart rate and contraction monitoring should be performed before and after the procedure to assess fetal well-being and the absence of contractions. If the decision is to perform intraoperative electronic fetal heart monitoring, then all the necessary provisions should be made to provide optimal safety for the mother and the fetus. These include availability of obstetric care providers, anesthesiologists, neonatologists, and nurses working as a team and ready to intervene during the surgical procedure for fetal indications. Informed operative consent should thus be obtained in anticipation for a possible emergency delivery.⁴⁷

Antepartum–intrapartum monitoring. In: Scott JR, DiSaia PJ, Hammond CB, et al., eds. *Danforth’s Obstetrics and Gynecology*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:243–255.)

IMAGING MODALITIES IN THE PREGNANT PATIENT

5 The most commonly used imaging modalities during pregnancy include radiography, ultrasonography, magnetic resonance imaging (MRI), and computed tomography (CT). The first and the latter are forms of ionizing radiation. The risks of ionizing radiation are an important source of anxiety for health care providers and patients that at times can force the physician to avoid the definitive diagnostic study of choice for fear that any radiation exposure would result in an anomalous fetus. This misconception could place both the mother and the fetus in greater danger from misdiagnosis. Although experimental data regarding the effects of ionizing radiation on the developing human fetus are impossible to obtain, animal exposure and follow-up of those inadvertently exposed to diagnostic and therapeutic radiation have provided some information. Retrospective studies of atomic bomb survivors in Hiroshima, Nagasaki, and victims of the atomic power plant disaster in Chernobyl have also allowed for evaluation of the effects of massive radiation exposure in utero.^{48,49}

Figure 106-3. Fetal heart variability. **A:** Short-term and long-term variability both absent: abnormal. **B:** Short-term variability present, long-term variability absent: abnormal. **C:** Long-term variability present, short-term variability absent: abnormal. **D:** Both

Ionizing Radiation

Fetal effects of ionizing radiation depend on the dose absorbed by the fetal tissue and the stage of fetal development during exposure. Exposure is defined as the amount of ionic charge created by the radiation on passing through a defined mass of air. Units traditionally used to measure the effects of ionizing radiation include the radiation absorbed dose (rad) and the roentgen equivalents man (rem). Modern units include the gray (Gy) and sievert (Sv). According to the International System of Units, Gy is the unit that describes the potential radiation exposure from medical diagnostic equipment, but rad is the predominant measure used. One gray (Gy) is strictly defined as the deposition of 1.0 joule of energy per kilogram of tissue, and 1 rad is 1% of 1 Gy. As a gross estimate, exposure to 1 roentgen gives an absorbed dose of 1 rad or 10 mGy.

Sv is generally used to measure the public exposure to radiation as it accounts for factors such as type of radiation amount of time exposed, level of protection, and distance from the radiation source. One sievert (Sv) = 1 Gy = 100 rads. It is a misconception to assume that the radiation dose that a pregnant woman is exposed to or absorbs is the same as that absorbed by the fetus as the latter is partially protected from radiation injury by a pregnant woman’s surrounding soft tissues and uterus, both of which generally stop alpha and beta particles from penetration if they are not ingested, injected, or inhaled.^{50,51} Radiographic evaluation of the abdomen and pelvis is most likely to expose the fetus to direct ionizing radiation, whereas examination of the extremities and chest leads to exposure from scatter radiation only (Table 106-1).⁵¹ The potential deleterious consequences of radiation-induced ionization of vital cellular structures can be divided into four categories: (1) lethal effects, (2) teratogenic effect, (3) growth retardation, and (4) oncogenic potential. The occurrence of each effect depends upon the gestational age at the time of radiation exposure, the dose of radiation absorbed by the fetus, and fetal cellular repair mechanisms. The first three categories of adverse pregnancy outcomes have a deterministic effect whereby a threshold or No-Adverse-Effect Level exists. After exceeding the No-Adverse-Effect Level, a deterministic effect generally shows a gradient relationship with the absorbed dose – the larger the absorbed dose, the more severe the effect. On the contrary, cancer appears to have a stochastic effect in which, the probability, but not the severity of the effect, increases with the radiation dose. Stochastic effects are monoclonal, resulting in changes to the cell genome and altered differentiation and function of the affected cells.

Lethal Effects of Ionizing Radiation

The developing human is most sensitive to the lethal effects of ionizing radiation during the first 14 days after conception (3 to 4 weeks of gestational age). During this period, the “all or none” principle applies to the radiation-exposed embryo; it either survives undamaged or succumbs. At that gestational age, a dose of 100 to 200 mGy (10 to 20 rad) can be lethal for an embryo. Shortly thereafter, the threshold for fetal death increases to 250 to 500 mGy (25 to 50 rad). The estimated radiation dose to kill all embryos or fetuses less than 18 weeks of gestational age is 5,000 mGy (500 rad). At term, the fetal risk equals the pregnant woman’s risk at 20,000 mGy (2,000 rad).^{52,53}

Table 106-1 Radiation Dosing to the Conceptus and Uterus from Selected Radiographic Examinations

Routine chest radiograph	8–50 mrad
Routine mammography <50 mrad	
Computed tomography, chest	25–1,000 mrad (uterus shielded and not exposed)
Computed tomography, upper abdomen	670–3,000 mrad (uterus shielded and not exposed)
Computed tomography, abdomen	2,000–3,000 mrad
Abdomen (flat plate) 250–300 mrad	
Endoscopic retrograde cholangiopancreatogra- phy with no permanent films and shielding of abdomen	4 mrad

Diagnostic modalities in the pregnant patient. *Emerg Med Clin North Am* 1994;12:9–43; and Baillic J, Cairns SR, Cotton PB. Endoscopic management of choledocholithiasis during pregnancy. *Surgery* 1990;171:1–4.

Teratogenic Effects of Ionizing Radiation

Teratogenic effects of radiation can be seen during early organogenesis in animal studies. Exposure of rats to 100 rads at various points of development reveals a very narrow window for teratogenesis. This window corresponds to weeks 2 to 4 in human development, consistent with early organ formation. Despite these experimental data, it is difficult to link any specific human malformation with radiation exposure other than those of the CNS. Microcephaly, pigmentary changes in the retina, hydrocephalus, and optic nerve atrophy have been reported at a significantly higher rate after exposure to radiation in pregnancy.⁵⁴ All patients were exposed to a minimum estimated dose of 100 rads, and no visceral, limb, or other malformations were found unless the child also exhibited CNS abnormalities. One explanation for this discrepancy is that the developmental period of the CNS is much longer, continuing throughout gestation and into the neonatal period, whereas other organs have a very narrow period during which morphologic alterations can be produced. Exposure to high doses of radiation during this narrow window is rare, and even if an isolated congenital abnormality were to occur, it would be difficult to separate this event from the background malformation rate. The extended period for CNS sensitivity to teratogenesis increases the prevalence of CNS malformation. Central nervous system malformation also occurs at threshold doses; however, low levels of exposure to 10 to 20 rads of radiation do not increase the incidence of microcephaly in experimental animals over baseline.⁵⁵

Growth Retardation from Ionizing Radiation

Growth retardation results from radiation-induced cellular depletion. Although catch-up growth can occur if exposure happens early in gestation, permanent cell depletion and growth retardation occur with exposure during later fetal stages.⁵⁶ Wood and colleagues⁵⁸ studied growth retardation of children exposed in utero to the Japanese atomic blasts. Those within 1,500 m from the center of the explosion were exposed to over 25 rads and, when followed through age of 17 years, were 2 to 3 cm shorter and 3 kg lighter and had a head circumference 1-cm smaller than normal. Those beyond 1,500 m from the blast received less than 25 rads and had a normal head circumference, height, and weight.^{52,57,58} Further, animal and human data support the contention that exposures of less than 5 rads should not cause either anatomic malformation or growth retardation.⁵⁵

Oncogenic Potential of Ionizing Radiation

The correlation between childhood cancer and in utero exposure to radiation has been demonstrated. Although conclusions regarding the cause-and-effect relationship of this correlation cannot be definitively established, further studies using twins⁵⁹ and extensive data analysis⁶⁰ have strengthened the argument that in utero radiation can increase the rate of childhood cancer even at doses of 1 rad. The current increase in childhood cancer is estimated at one to two cases per 3,000 children exposed to 1 rad in utero.⁵⁷ Although these risks are very small, the patient must be counseled regarding this potential danger. By reviewing the current data, it is obvious that exposure to diagnostic levels of radiation carries little chance for spontaneous abortion, teratogenesis, or growth retardation. The increased risk of future cancer, however, does exist and must be weighed against the utility of the information provided by the study.

Ultrasound

Ultrasonography uses high-frequency, acoustic radiation to create images. A surface transducer containing piezoelectric crystals converts electrical energy into sound waves. Sound waves pass through tissue layers and are reflected back to the transducer when they encounter an interface between tissues of different densities. Digital images generated at 50 to more than 100 frames per second undergo postprocessing that produces the appearance of real-time imaging. Ultrasonography is considered the first-line diagnostic imaging modality of the pregnant surgical patient because it is nonionizing, widely available, portable, and of adequate diagnostic performance. This imaging technique has been used in obstetrics for more than 50 years without reported fetal damage or harmful effects.^{61,62} Ultrasonography is, however, a form of energy with effects on tissues through which the waveform penetrates. The two major mechanisms involved in potentially causing bioeffects are direct, resulting from the alternation of positive and negative pressures (mechanical or cavitation effects) and indirect, caused by heating of tissues secondary to transformation of the acoustic energy (thermal effects). Because of these theoretical concerns, several organizations have recommended that this diagnostic procedure should be performed only when there is a valid medical indication and the lowest possible ultrasonic exposure setting under the as low as reasonably achievable principle.^{63–65}

Computed Tomography

In the past 10 years, the use of radiologic examinations in pregnant women has increased by 107%, with the greatest increase occurring in the use of CT.⁶⁶ Computed tomography is most valuable in the second and third trimesters, when ultrasonography is of limited value, in a patient with a large body habitus, and when MRI is inconclusive or not available.⁶⁷ Because of its sensitivity for the detection of abdominal and pelvic injury as well as retroperitoneal injury in which the clinical urgency requires prompt diagnosis, CT is the test of choice for injured pregnant patients.^{68–70} When CT is performed during pregnancy, using dose-reduction protocols (e.g., abdominal and internal barium shielding) results in significant reduction in the probability of biologic effects to the fetus without sacrificing the necessary diagnostic image quality.⁷¹

Magnetic Resonance Imaging

Like ultrasonography, MRI uses no ionizing radiation, instead relying on the magnetic properties of tissues to create images. Four magnetic fields interact during an MRI examination to create the image. The intrinsic magnetic field of an atomic nucleus, usually that of a hydrogen proton, is combined with a strong, uniformly applied external magnetic field and a weaker magnetic field gradient. In addition, a magnetic field is intermittently generated by pulsed radio frequency waves.⁵² When the radio frequency ceases, the nuclei return to their previous orientation and emit the radio frequency they absorbed. These signals are detected, stored, and processed by a computer to create an image. Theoretical concerns include the effects of fluctuating electromagnetic fields and high sound intensity levels with potential damage to the fetal ear. Other known dangers of MRI exposure include trauma from projection of small metal fragments into the eyes, interference with the operation of implantable electronic devices, position of metallic implants, and burns from heating of conductive materials in implants. Despite these concerns, present data have not conclusively documented any deleterious effects of MRI exposure on the developing conceptus or the pregnant woman.⁷²

PHYSIOLOGIC CHANGES OF PREGNANCY THAT MIMIC DISEASE

Pregnancy physiology reflects the changes necessary for fetal gestation. It is characterized by the enlarging, gravid uterus and a changing hormonal milieu. These conditions predispose to certain diseases and change maternal physiology to mask the diagnosis of others. The cardiovascular system is affected by pregnancy. The cardiac output increases by 30% to 50%, as does the total blood volume. The corresponding red blood cell volume increases only by 20% to 30%, leading to a decrease in the hematocrit. Although the maternal oxygen-carrying capacity is increased and the rheologic properties of blood are optimized for maximum nutrient delivery to the fetus, a physiologic anemia develops that can be confused with a pathologic state.⁷³ Diagnosis of anemia due to chronic blood loss, as occurs with cancers of the gastrointestinal tract, may be delayed as the gradually decreasing hematocrit is attributed to pregnancy. Other laboratory evaluations can also mask various disease states (Table 106-2). Serum alkaline phosphatase levels gradually increase because of production of an alkaline phosphatase isozyme

by the placenta. This does not reflect biliary or bone disease. Albumin levels, commonly used to measure hepatic synthetic function, decrease, and a relative leukocytosis mimics a systemic infection.

Table 106-2 Change During Pregnancy in Laboratory Values

Parameter	Change	Normal Nonpregnant Value	Late Pregnancy Value
Albumin (g/dL)	↓	3.2–3.8	2.4–3.1
Alkaline phosphatase (IU/L)	↑	30–115	100–210
Total bilirubin (mg/dL)	↔	0.26–1.00	Unchanged
Aspartate amino-transferase (IU/L)	↔	0–31	Unchanged
Hemoglobin (g/dL)	↓	12.0–16.0	10.5–14
Leukocyte count ($\times 10^3/\text{mm}^3$)	↑	4.5–11.0	6.0–16.0

↑, up; ↓, down; ↔, no change. Reproduced from Martin C, Varner MW. Physiologic changes in pregnancy surgical implications. *Clin Obstet Gynecol* 1994;37:241–255, with permission.

The gastrointestinal tract undergoes a state of relaxation and decreased smooth muscle activity during pregnancy. The lower esophageal sphincter tone gradually decreases, as does gastric emptying. Prolonged small bowel transit time and decreased colonic emptying not only work to maximize nutrient and water absorption but also contribute to the constipation reported by 38% of pregnant women.⁷⁴ Although multifactorial, the actions of progesterone have been linked to inhibition of gut smooth muscle activity both in vitro and in vivo. Because this dose-dependent inhibition can be blocked by increasing the extracellular concentration of Ca^{2+} , at least in vitro, it is proposed that progesterone works by limiting the effective Ca^{2+} available for actin–myosin coupling.^{75,76} This same mechanism contributes to uterine relaxation early in pregnancy, decreased intestinal motility, and the concurrent decrease in gallbladder tone and rate of emptying. With these changes, combined with supersaturation of bile by cholesterol, pregnancy becomes a lithogenic state.⁷⁷ These effects of pregnancy are transient and gallbladder motility and volumes return to normal as early as 2 weeks after pregnancy, but the gallstones, if formed, may persist. Nausea and vomiting of pregnancy is a common occurrence affecting between 50% and 90% of all women.^{78,79} These symptoms rarely extend beyond the first trimester. Other causes must be investigated if the nausea and vomiting occur later in pregnancy. Abdominal pain, although often due to a surgical pathologic process, can have many causes. Round ligament pain is described as an aching, dragging pain more often felt on the right side. It is a common occurrence until 31 weeks of gestation. Pain in the hypochondrium can result from uterine pressure on the lower ribs, and lower abdominal pain may be psychogenic, related to anxiety about the pregnancy or insecurity over the social situation.⁸⁰ It is up to the surgeon to determine the cause of abdominal pain in the pregnant patient and decide the course of diagnosis and intervention.

APPENDICITIS IN THE PREGNANT PATIENT

6 Acute appendicitis is the most common nonobstetric cause of acute surgical abdomen during pregnancy.⁸¹ Disease is confirmed in 65% to 75% of suspected cases for an incidence of approximately 1:1,500 births.⁸² Although previous series suggested that the condition had similar incidences for nonpregnant adults, equal distribution throughout pregnancy,⁸³ and a more common occurrence later in gestation,^{84,85} a recent large case-control study indicated a lower incidence than among nonpregnant individuals, particularly in the third trimester.⁸⁶ The incidence decreases in the third trimester to 15% to 30% compared to rates ranging from 20% to 60% in the first and second trimesters.^{87,88} A well-known fact is that the anatomic and physiologic changes of the gravid state make the diagnosis difficult. Attributing abdominal pain to other etiologies (e.g., pyelonephritis, false labor, and gastroenteritis), failure to pursue further investigation, and the physicians' fear of surgically induced premature labor all contribute to delayed diagnosis and timely appendectomy in pregnancy. Appendiceal perforation rates are higher when compared with those from nonpregnant populations (55% vs. 4% to 19%).⁸⁹ This is probably explained by confounding variables leading to the delay of diagnosis and therapy. Several

series have documented a correlation between a delay in the diagnosis and gestational age. In the first trimester, most diagnoses were made promptly and significant delay in operation with a rate of perforation of 49% reported for patients presenting in the second trimester and a rate as high as 70% for those presenting in the third trimester.^{83,90} Perforated appendicitis presents a greater infectious risk in the pregnant patient than in the population as a whole. The large uterus interferes with proper omental migration throughout the abdominal cavity and prevents the walling off of the inflammatory process. Braxton Hicks contractions disrupt adhesion formation, and the general increase in vascularity of the abdomen with greater lymphatic drainage allows rapid dissemination of infection. The high circulatory levels of adrenocorticoids in pregnancy have also been hypothesized to diminish the tissue inflammatory response and hinder containment of infection.^{91–93} All of the classic signs and symptoms of appendicitis are altered by pregnancy (Table 106-3). Anorexia, nausea, and vomiting occur in 58% to 77% of pregnant patients with appendicitis.^{83,90} Although anorexia, nausea, and vomiting in the first trimester are common, their occurrence during the second and third trimesters, especially if associated with abdominal pain, require a thorough investigation. In a classic 1932 study, Baer and colleagues⁹⁴ evaluated the migration of the appendix through the duration of pregnancy with barium enemas. Beginning in the first trimester, the appendix and the cecum are gradually displaced by the uterus and start a caudal migration out of the pelvis into the upper abdomen. By the third trimester, the appendiceal tip can abut the gallbladder (Fig. 106-4). The vague, referred epigastric pain due to early appendiceal obstruction is not changed by this anatomic consideration, but the location of the somatic pain is. In a large study of pregnant women with proven appendicitis, abdominal pain was present in all patients. Location of pain in the right lower quadrant, however, was common only early in gestation, and a portion of patients reported pain in the right upper quadrant. This change in symptomatology is easily understood if the anatomic changes of the appendix are taken into consideration.⁸³ Both guarding and rigidity are valuable findings on physical examination but are common only in the first trimester. Elevation of the abdominal wall from the more laterally placed, upward-directed appendix and the laxity of the abdominal wall musculature caused by this distention decrease the reliability of these findings. Only 42.9% of patients in the third trimester are reported to have abdominal spasm and guarding, compared with 80% during the first trimester.⁹⁵ Psoas and obturator signs are similarly obscured as the appendix is moved from its normal location and have not been shown to have clinical significance. The results of laboratory examinations commonly used to assist in the diagnosis of appendicitis are also obscured by pregnancy. The physiologic leukocytosis of pregnancy, ranging from 5,000 to 12,000 white blood cells (WBCs)/mL, overlaps that of appendicitis. In one collected series, the WBC count of pregnant patients with proven appendicitis was not significantly elevated over these values, and only 25% of patients had a WBC count over 15,000. Most patients (50%) had WBC counts ranging between 10,000 and 15,000, and 25% had less than 10,000 WBCs/mL.⁸³ Urinalysis is a useful adjunct in the workup of appendicitis but again presents a dilemma in pregnancy. Urinary tract infection is common in pregnancy as the enlarging uterus compresses the right ureter. Dilatation and stagnant flow in the right collecting system can contribute to bacterial overgrowth and infection. Pyuria without bacteria can also indicate involvement of the right ureter in the appendiceal inflammatory process. The presence of pyuria and bacteriuria does not rule out appendiceal inflammation because the two conditions may coexist in 40% of pregnant patients.⁹⁰ The risk of adverse pregnancy outcomes after appendectomy during pregnancy has been reported by two large population-based studies. From the California Inpatient File of 3,133 pregnant women undergoing surgery for suspected appendicitis, the fetal loss rate was 23%, and it was doubled – 6% versus 11% – with simple versus complicated disease.⁹⁶ In the other study, the fetal loss rate within 1 week of the procedure was 22%, particularly when the surgery was performed after 23 weeks.⁸² Fortunately, these same researchers noted no additional increase in the preterm birth rate among the pregnancies that continued beyond the first postoperative week. Perforated appendicitis in pregnancy rapidly leads to diffuse peritonitis, premature labor, and fetal loss.^{85,97}

Table 106-3 Variation in Signs and Symptoms of Appendicitis During Pregnancy

Signs and Symptoms	First Trimester	Second Trimester	Third Trimester
Right lower quadrant pain	100%	50%	14%
Right upper quadrant pain	0%	17%	57%
Guarding (muscle spasm)	80%	50%	43%
Nausea and vomiting	53%	60%	23%
Tenderness on rectal examination	60%	17%	0%
Perforation rate	20%	49%	70%

Figure 106-4. Changing location of the appendix throughout gestation.

IMAGING MODALITIES

Ultrasonography is the initial nonionizing imaging modality of choice in these patients. Findings suggesting appendicitis include visualization of a tubular structure with a diameter of more than 6.0 mm, a wall thickness of more than 3.0 mm, and lack of peristalsis (Fig. 106-5).^{98,99} One study reviewed the value of ultrasonography in diagnosing appendicitis in pregnancy. That review reported a range of sensitivity of 67% to 100% and a range of specificity of 83% to 96%, compared to diagnostic performance in the general population of 86% and 96%, respectively.¹⁰⁰ Ultrasonography, however, does have limitations due to body habitus, intraluminal air, and operator level of experience. The examination can also be difficult because of abdominal guarding and pain during examination. Distortion of anatomic landmarks and the displacement of the appendix by the gravid uterus complicate the diagnosis. Other structures such as an inflamed salpinx can also mimic appendicitis on ultrasonogram,¹⁰¹ and a dilated uterine vein during pregnancy has been mistaken for an acutely inflamed appendix.¹⁰² Chest radiography should be considered in the evaluation of patients with suspected appendicitis because right lower lobe pneumonia may manifest with lower abdominal pain. Abdominal plain films are usually avoided unless there is suspicion for visceral perforation or bowel obstruction. Computed tomography has emerged as a highly reliable modality in the diagnosis of appendicitis. Appendiceal CT, using rectally administered contrast, can be performed within 10 to 20 minutes, does not require a waiting period for oral contrast to progress down through the cecum, and exposes the patient to only one-third the radiation of a regular CT scan.¹⁰³ Computed tomography in the

nonpregnant population is more sensitive and specific than sonography (approximately 98% each) to confirm suspected appendicitis.¹⁰⁴ A computed tomographic scan is considered abnormal if there is an enlarged appendix (>6 mm in maximum diameter) or if there are periappendiceal inflammatory changes such as fat stranding, phlegmon, fluid collection, and extraluminal gas. Routine use of this modality has been shown to reduce costs, expedite the diagnosis, and reduce perforation rates from 22% to 14% while decreasing the incidence of negative laparotomy from 20% to 7%.^{105–107} Radiation exposure is 300 mrad with a limited helical CT scan, which is one-third of the amount of the average abdominopelvic CT scan.¹⁰⁸ Because even low levels of radiation in utero can increase the incidence of childhood cancer, widespread use of this modality in the pregnant patient with abdominal pain may be detrimental. Reserving the CT scan for those cases in which the clinical history, physical examination, and ultrasonography are indeterminate should decrease the rate of perforation and negative exploration, just as it has in the nonpregnant population (Fig. 106-6). MRI uses nonionizing radiation, has no known adverse fetal effects, and, like CT, has the potential to image the whole abdomen. On MRI an appendix is considered abnormal when it is fluid-filled, greater than 6 or 7 mm in diameter, or demonstrates the presence of periappendiceal inflammatory changes. A study suggested that a normal appendix on MRI had a high specificity (98% to 100%) and a high negative predictive value (94% to 100%) in excluding acute appendicitis.¹⁰⁹ The American College of Radiology guidance documented MRI safe practices 2013 and reaffirmed its use in pregnancy if considered necessary irrespective of gestational age. Intravenous gadolinium contrast has no known adverse effects in humans but its use should be based on whether the potential benefits to the patient exceed the theoretical risks to the fetus.¹¹⁰

Figure 106-5. Ultrasonographic appearance of appendicitis. The appendix appears as a thick, noncompressible tubular structure with central hypoechogenicity. The walls are 5-mm thick, over the 3-mm limit for a normal appendix. (Courtesy of Dr. Beverly Coleman, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

Laparoscopy

Laparoscopy to evaluate the appendix is a feasible diagnostic modality during pregnancy but may be difficult during later gestation. Anatomic changes alter placement of trocars above the gravid uterus¹¹¹ and require the use of the open Hasson technique of trocar placement under direct visualization rather than blind insufflation with a Veress needle. Maneuvers to enhance operative safety of laparoscopy in pregnancy have been outlined by the Society of American Gastrointestinal Endoscopic Surgeons (Table 106-4).¹¹²

Figure 106-6. Computed tomographic (CT) scan of a woman in the 18th week of gestation presenting with a 12-hour history of right-sided abdominal pain. Abdominal examination on presentation revealed significant tenderness, and after a nondiagnostic ultrasonography, a laparotomy is considered for presumed appendicitis. A CT scan is obtained instead, revealing a normal, air filled appendix with no sign of periappendiceal inflammation (*arrow*). The laparotomy was postponed, and 12 hours later the patient aborted a septic fetus. An unnecessary laparotomy for an atypical presentation of chorioamnionitis was avoided by the judicious use of the CT scan. (Courtesy of Dr. David Weiss, Chestnut Hill Hospital, University of Pennsylvania Health System, Philadelphia, PA.)

Appendectomy

Once the diagnosis of appendicitis is made, treatment is strictly surgical. If an open procedure is chosen, a muscle splitting incision is made over the point of maximum tenderness because the appendix customarily lies beneath that point.^{81,83,90} A right paramedian incision usually necessitates medial retraction of the uterus for exposure and increases the risk of precipitating premature labor. By tilting the patient 30 degrees to the left, the uterus is shifted away from the operative field and off the inferior vena cava. Because of the migration of the appendix, an incision over McBurney point in the late second and third trimesters is inadequate. If diffuse peritonitis is present, a midline incision is usually performed. Perforated appendicitis or pus in the abdominal cavity demands thorough peritoneal toilet along with the appendectomy. A periappendiceal abscess can be treated with percutaneous drainage, followed by an interval appendectomy 2 to 3 months later.¹¹³ Perioperative antibiotics should be administered to cover gram-negative bacteria and anaerobes, usually a second- or third-generation cephalosporin, expanded-spectrum penicillin, or even triple agent therapy.¹¹⁴ Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Seldom is cesarean delivery recommended at the time of appendectomy. Although uterine contractions are common, tocolytic therapy is generally not recommended. If exploration reveals a normal appendix, an appendectomy still should be performed. Although some authors question this approach because of the suggested high rate of preterm labor with a normal appendectomy,¹¹⁵ most believe this to be untrue. Taking out the normal appendix adds little to morbidity while eliminating potential confusion if symptoms should recur.⁸³ Since it was first performed in 1980, laparoscopic appendectomy in pregnancy has spawned controversy, which continues to this date. Its use in pregnancy has been recently documented with a good safety record.¹¹⁶ It has a complication rate similar to that for nonpregnant laparoscopy.¹¹⁷ Its major advantages over open appendectomy include less abdominal wall trauma, less pain and narcotic use, and faster return to normal activity. However, the presence of the enlarged uterus does increase the risk of inadvertent puncture with a trocar or Veress needle.¹¹⁸ In the second half of pregnancy, open laparoscopy may be preferred to avoid such complications. Unlike nonpregnant laparoscopy, no instrument should be applied to the cervix. The primary trocar is inserted after determining the size of the uterus, and the secondary trocars are inserted under direct visualization. Consideration of supraumbilical, subxiphoid insertions may be necessary. Limiting intra-abdominal pressures to less than 12 mm Hg and reducing operative time can reduce concerns about maternal hypercarbia and subsequent fetal acidosis. Laparoscopy is almost always used to treat suspected appendectomy during the first two trimesters. There were similar perinatal outcomes from the Swedish database of nearly 2,000 laparoscopic appendectomies compared with those of more 1,500 open laparotomies done before 20 weeks.¹¹⁹ Conversely from their review, Wilasrusmee and coworkers¹²⁰ reported a higher fetal loss with laparoscopy.

Table 106-4 Guidelines for Laparoscopic Surgery during Pregnancy

1. Diagnostic laparoscopy is safe and effective when used selectively in the workup and treatment of acute abdominal processes in pregnancy.
2. Laparoscopic treatment of acute abdominal disease has the same indications in pregnant and nonpregnant patients.
3. Laparoscopy can be safely performed during any trimester of pregnancy.
4. Gravid patients should be placed in the left lateral decubitus position to minimize compression of the vena cava.
5. Initial abdominal access can be safely accomplished with an open (Hasson) technique, Veress needle, or optical trocar, if the location is adjusted according to fundal height and previous incisions.
6. CO₂ insufflation of 10–15 mm Hg can be safely used for laparoscopy in the pregnant patient.
7. Intraoperative CO₂ monitoring by capnography should be done during laparoscopy in the pregnant patient.
8. Intraoperative and postoperative pneumatic compression devices in early postoperative ambulation are recommended prophylaxes for deep venous thrombosis in the gravid patient.
9. Laparoscopic cholecystectomy is the treatment of choice in the pregnant patient with gallbladder disease, regardless of trimester.
10. Cholelithiasis during pregnancy may be managed with preoperative endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy, followed by laparoscopic cholecystectomy, laparoscopic common bile duct exploration, or postoperative ERCP.
11. Laparoscopic appendectomy may be performed safely in pregnant patients with appendicitis.
12. Obstetric consultation can be obtained pre-and/or postoperatively on the basis of the severity of the patient's disease, gestational age, and availability of the consultant.
13. Tocolysis should not be used prophylactically in pregnant women undergoing surgery but should be considered perioperatively when signs of preterm labor are present.

Modified from SAGES Committee on Standards Practice. Guidelines for laparoscopic surgery during pregnancy. *Surg Endosc* 2011;25:2479–3492.

BILIARY TRACT DISEASE IN PREGNANCY

7 After appendicitis, acute cholecystitis is the second most common nonobstetrical indication for surgery in pregnant women and the most common cause of maternal hospitalization in the first year after delivery.¹²¹ Pregnancy and the postpartum period appear to predispose women to gallstone formation. This is attributed to increase in sex steroid hormone levels in pregnancy, causing biliary stasis, prolonged intestinal transit, and increased cholesterol saturation of bile. Multiparity and prepregnancy obesity are the two major independent risk factors for cholelithiasis in pregnancy. One study found that gallstones occurred in 7% of nulliparous women, with the rate rising to 19% of women with two or more pregnancies. This risk of gallstones appears to increase during gestation, with sludge or stones found in 5.1% of 3,254 prospectively studied women in the first trimester, 7.9% in the second trimester, and 10.4% by 4 to 6 weeks after delivery.¹²² However, among women with sludge or stone, only 1.2% developed any symptoms attributable to the gallbladder during pregnancy.¹²³ Despite the predilection for stone formation in pregnancy, acute cholecystitis does not occur more frequently during pregnancy. Data suggest that cholecystitis affects only 0.1% of pregnant women.¹²⁴ Most patients with symptomatic gallstones present with complaints of biliary colic likely resulting from gallbladder contractions and increased pressure and luminal expansion characteristically exacerbated by a fatty meal. These patients often complain of epigastric or right upper quadrant pain. The onset of pain is typically between 1 and 3 hours postprandially. The discomfort progresses in less than an hour to a steady plateau that ranges from moderate to excruciating and remains constant for more than an hour and then subsides slowly over several hours. Less frequently, the symptoms are those of one of the complications of gallstones, acute cholecystitis, cholangitis, or pancreatitis. Signs and symptoms may include right upper quadrant pain, fever, tachycardia, leukocytosis, anorexia, and vomiting. Sepsis and jaundice may also be seen. Abdominal examination usually demonstrates voluntary and involuntary guarding and frequently a positive Murphy sign. Laboratory studies should be normal in patients with uncomplicated cholelithiasis. However, mild elevations in serum aminotransferases and amylase may occur as a result of the passage of small stones or sludge. Significant elevations in aminotransferases, hyperamylasemia, increased direct bilirubin, and alkaline phosphatase may be signs of complicated gallbladder disease. The differential diagnosis includes appendicitis, pancreatitis, peptic ulcer disease, pyelonephritis, right-sided pneumonia, acute fatty liver of pregnancy, and preeclampsia. Abdominal ultrasound is a reliable diagnostic tool for identifying gallstones, sludge, and acute or chronic cholecystitis with a high sensitivity and specificity.¹²⁵ A diagnosis of acute cholecystitis is suspected by findings of gallbladder distention, gallbladder wall thickening, and pericholecystic fluid on ultrasonography.¹²⁶ Transabdominal ultrasonography is relatively insensitive for the detection of common bile duct stones, whereas endoscopic ultrasound is highly accurate for that purpose. Magnetic resonance cholangiopancreatography (MRCP) may be used when extrahepatic ductal stones are suspected or in complicated cases when ultrasound is nondiagnostic. Endoscopy of the biliary system by endoscopic retrograde cholangiopancreatography (ERCP), with its associated radiation exposure, can be performed safely in pregnant patients but should be limited to cases in which treatment of ductal stones is

required. The appropriate management for symptomatic cholelithiasis and acute cholecystitis during pregnancy is controversial. Suggested management for a pregnant patient with symptomatic cholelithiasis during the first trimester consists of conservative measures until elective cholecystectomy can be performed safely during the second trimester. Traditional supportive care includes withdrawal of oral food and fluids, pain control, intravenous fluids, and nasogastric aspiration depending upon the clinical presentation. However, nonoperative management of symptomatic cholelithiasis is associated with significant recurrence bouts of symptoms, prolonged total parenteral nutrition, higher rates of preterm delivery, cesarean section, and more technically difficult cholecystectomies compared with laparoscopic cholecystectomy.¹²⁷⁻¹²⁹ Cholecystectomy can be performed safely and effectively during pregnancy in all trimesters. Either an open or laparoscopic approach may be chosen; however, laparoscopic cholecystectomy is the preferred technique for removal of the gallbladder in pregnant women. Overall, patients have a shorter postoperative stay, resume oral intake earlier, have fewer postoperative hernias, and experience less pain with lower narcotic requirements by avoiding a large open incision.¹³⁰⁻¹³² Because fetal loss is most likely related to the underlying maternal illness and extent of uterine manipulation during surgery,^{133,134} laparoscopic cholecystectomy offers a solution to both problems. Based on the available data, laparoscopic cholecystectomy is safe during pregnancy and is preferable to open cholecystectomy.¹³⁵ Removing the diseased gallbladder eliminates the potential for recurrence, and the minimal uterine retraction needed with laparoscopic access to the right upper quadrant should decrease the risk for preterm labor. After an open cholecystectomy, the reported rate of premature labor ranges from 0% to 40%, based on trimester,¹³⁶ and a spontaneous abortion or premature birth rate of up to 22% has been reported.¹³⁷ The incidence of premature uterine contractions with laparoscopic cholecystectomy has been reported at 0% to 21%, but contractions are usually well controlled by tocolytics. Most series report rates of premature birth or spontaneous abortion ranging from 0% to 7% with the laparoscopic approach.^{111,133,134} The second trimester is the optimal time to perform an elective cholecystectomy. Organogenesis is complete and the gravid uterus is not yet large enough to impinge on the operating field.¹³⁸ Those patients presenting later in gestation can probably be managed symptomatically until the postpartum period, with cholecystectomy generally performed 6 weeks following delivery to allow the mother to recover and to bond with her infant.

Choledocholithiasis

Indications for evaluation of the common bile duct are no different in the pregnant patient than in the population as a whole – namely, a bilirubin elevated over 1.5 mg/dL, a dilated common bile duct, or gallstone pancreatitis.¹¹¹ ERCP can be performed in pregnancy. With proper lead shielding, judicious use of fluoroscopy time, and avoidance of permanent roentgenographic films, ERCP has been performed with no direct exposure of the fetus to radiation. Calculated scatter radiation on the order of 4 mrad during the whole examination presents the only risk from ionizing radiation.¹³⁹ Evaluation of the biliary tree, stone retrieval, and sphincterotomy can be performed under these conditions without maternal or fetal complications.¹⁴⁰ Other methods avoid radiation altogether and include imaging of choledocholithiasis with endoscopic ultrasonography,¹⁴¹ endoscopic papillotomy under ultrasonographic control,¹⁴² and MRCP for choledocholithiasis.¹⁴³ Success with all these modalities has been reported but can be limited by operator experience and availability.

INTESTINAL OBSTRUCTION DURING PREGNANCY

8 The incidence of intestinal obstruction during pregnancy rose throughout the 20th century. In the presurgical era, cases were cited as infrequently as 1:68,000 deliveries. Since the 1940s, however, the incidence has increased to 1:2,500 to 3,500 deliveries.^{144,145} This change reflects the increased number of pelvic and abdominal surgeries in young women that includes cesarean deliveries.¹⁴⁶⁻¹⁴⁸ Adhesions remain the most common cause of intestinal obstruction in the gravid patient, but intestinal volvulus is a much more common complication than that in the population as a whole. Intussusception, hernia, and carcinoma are responsible for a minority of cases of bowel obstruction (Table 106-5). The incidence of adhesion-related obstruction is highest during the first pregnancy after an operation, when the association between the viscera and adhesions is initially tested. Most cases of intestinal obstruction during pregnancy result from pressure of the growing uterus on intestinal adhesions. According to Davis and Bohon, this likely occurs (1) around midpregnancy, when the uterus becomes an abdominal organ; (2) in the third trimester, when the fetal head descends; or (3) immediately postpartum, when there is

an acute change in uterine size.^{144,145}

In the general population, incarceration of bowel in groin hernias is the second most common cause of small bowel obstruction, but in the pregnant patient, volvulus becomes the number 2 cause. Sigmoid volvulus, the most common site of volvulus during pregnancy, normally occurs owing to a long and redundant sigmoid colon.¹⁴⁹ Anatomic changes of pregnancy further exacerbate this condition by causing the redundant sigmoid colon to rise out of the pelvis and twist around its point of fixation.^{150,151} Cecal volvulus occurs because of failure of lateral peritoneal fixation during development. As the uterus enlarges during pregnancy, it raises the redundant or abnormally mobile cecum out of the pelvis. If a transition point or distal obstruction should occur from uterine pressure or an adhesive band, the colonic distention raises the colon even higher, producing torsion around this fixed point.¹⁵² Volvulus of the small bowel can also result from a congenital abnormality of rotation and fixation. The enlarging uterus potentially predisposes to the presentation of this anomaly during pregnancy by pushing the nonfixed, mobile portions of the small bowel into the upper abdomen, initiating the volvulus.^{153,154}

Table 106-5 Causes of Intestinal Obstruction Complicating Pregnancy and the Puerperium in 66 Patients

Adhesions	39 (59%)
Volvulus	15 (23%)
Sigmoid	7
Cecal	3
Midgut	3
Volvulus around vitellointestinal band	2
Intussusception	3 (5%)
Hernia	2 (3%)
Carcinoma	1 (1%)
Appendicitis	1 (1%)
Idiopathic (ileus)	5 (8%)

Reproduced from Perdue PW, Johnson HW, Stafford PW, et al. Intestinal obstruction complicating pregnancy. *Am J Surg* 1992;164:385, with permission.

Presentation and Diagnosis

Perdue¹⁴⁹ reported that 98% of pregnant women had either continuous or colicky abdominal pain, and 80% had nausea and vomiting, symptoms that are similar to those in the nonpregnant patient. Abdominal tenderness was found in 70%, and abnormal bowel sounds noted in only 55%.¹⁴⁹ High small bowel obstruction results in short periods between vomiting episodes with poorly localized, crampy upper abdominal pain. Colonic obstruction can present with less frequent, feculent vomiting and lower abdominal pain. Findings on physical examination such as abdominal distention are often difficult to evaluate because of the gravid uterus. Obstipation, although characteristic of low obstruction such as that of sigmoid volvulus, may not occur with high obstruction. Laboratory studies, although useful to rule out other conditions, are not reliable enough to be considered diagnostic of obstruction. Significant leukocytosis can occur with necrosis and bowel strangulation, but mild elevations are confusing because of the physiologic leukocytosis of pregnancy. Tachycardia and hypotension are also late signs suggesting bowel compromise and shock. The murky clinical picture combined with the tendency to treat the progressive vomiting as a normal part of pregnancy and crampy abdominal pain as early contractions lead to a delay in presentation and diagnosis. The median time from the onset of symptoms to admission in one series was 48 hours, and the median time from admission to a necessary laparotomy was also 48 hours. This delay in diagnosis and treatment contributed to excessive maternal and fetal mortality.¹⁴⁹ Abdominal pain and vomiting in a pregnant patient with an abdominal scar should raise the serious suspicion of small bowel obstruction. If intestinal obstruction is suspected, upright and flat films of the abdomen are the diagnostic studies of choice. Serial films obtained every 4 to 6 hours usually show progressive changes confirming the diagnosis.¹⁴⁴ Small bowel obstruction gives the appearance of a progressive stepladder formation with dilatation and multiple air–fluid levels. Large bowel obstruction can produce a similar picture or reveal a grossly dilated bowel loop suggestive of volvulus. Contrast studies are also useful, and a “bird’s bill” shape of contrast with gradual narrowing after a barium enema can be diagnostic of colonic volvulus, whereas dilute Gastrografin or barium by mouth can usually differentiate partial from complete obstruction. Fetal radiation risks from the plain

radiographs are negligible and greatly outweighed by those from the possibility of misdiagnosis. Because plain radiographs are less accurate for diagnosing small bowel obstruction, CT and MRI can be diagnostic.^{155,156} Colonoscopy can be both diagnostic and therapeutic for colonic volvulus.^{157–160} During pregnancy, mortality rates with obstruction can be excessive because of difficult and thus delayed diagnosis, reluctance to operate during pregnancy, and the need for emergency surgery.^{161,162} Perdue and Johnson¹⁴⁹ described a 6% maternal mortality rate and a 26% fetal mortality rate. Two of the four women who died were in late pregnancy, and they had sigmoid or cecal volvulus caused by adhesions.¹⁴⁵

Treatment

The initial treatment of bowel obstruction in the pregnant patient is no different from that in a nonpregnant patient. Nasogastric tube decompression and fluid resuscitation are the cornerstones of therapy. By the time an obstruction is visible on plain film, the fluid deficit due to vomiting and intraluminal losses is estimated at 1,000 to 1,500 mL. In advanced cases of dehydration presenting with tachycardia and hypotension, fluid losses may be as high as 4 to 6 L.¹⁴⁴ Prompt fluid resuscitation is essential in the pregnant patient because compromise of uterine blood flow leads to fetal compromise and demise. Surgical intervention plays a more prominent and earlier role in the management of the pregnant patient with bowel obstruction. Although adhesion-related small bowel obstruction in the nonpregnant patient usually resolves with nasogastric decompression and fluid administration, numerous series have documented failure of conservative management of small bowel obstruction in the pregnant woman. Eighty-nine percent to 100% of patients eventually require an operation, and 13% to 23% require resection of gangrenous bowel at the time of laparotomy.^{151,156} Based on these outcomes, some have stated that once the diagnosis of small bowel obstruction is made in a pregnant patient, the only role of nasogastric decompression and fluid resuscitation is to prepare the patient for an operation.¹⁵¹ Cecal volvulus is also treated surgically, and although sigmoid volvulus in the nonpregnant patient can be managed with sigmoidoscopic decompression and placement of a rectal tube, the large gravid uterus may act as a mechanical impediment to detorsion. A laparotomy is usually necessary for the treatment.^{145,155} A generous midline incision allows for maximum exposure of the abdomen with minimal manipulation of the uterus. During lysis of small bowel adhesions, bowel viability must be carefully assessed. Definitive management of cecal volvulus requires resection of necrotic cecum or detorsion and cecopexy. Sigmoid volvulus should also be treated by resection if necrotic but simple detorsion and placement of a rectal tube can be performed if the sigmoid is viable. Although resection of the redundant sigmoid is the definitive treatment of this disease, it can be delayed until the postpartum period. Aggressive surgical treatment has been credited with reducing the maternal and fetal mortality rates from 20% and 50%, respectively, in the 1930s to 6% and 26% today.¹⁵¹ Increased awareness of this disease and expeditious management can reduce those rates even further.

COLORECTAL CANCER DURING PREGNANCY

9 Colorectal cancer is the third most frequent malignancy in women of all age groups in the United States,¹⁶¹ but it rarely complicates pregnancy because it is uncommon before 40 years of age. The mean age at diagnosis of colorectal cancer in pregnancy is 31 years (range 16 to 48 years).¹⁶² The incidence of colon cancer was estimated as 1:50,000 pregnancies based on a 1955 report.¹⁶³ More recent reviews estimate the incidence as 1:13,000 deliveries,¹⁶⁴ with the increasing prevalence of colorectal cancer diagnosed during gestation due to the current trend of delaying pregnancy into the later reproductive years.¹⁶⁵ The majority of colorectal carcinoma in pregnant women arise from the rectum. This location is at odds with the pattern seen both in the general population and in nonpregnant patients younger than 40 years in whom, as reported by the American Cancer Society in 1981, 69% of tumors were in the colon and 31% in the rectum.¹⁶⁶ On reviewing more than 200 published cases of colorectal cancer in pregnancy, it was noted that 86% occurred below the peritoneal reflection and were thus rectal tumors.¹⁶² The observed deviation from the usual tumor distribution is likely attributed to detection bias because of the increased frequency of pelvic examinations in the prenatal period or the change in pelvic anatomy and symptoms of rectal compression by the gravid uterus. Pregnant patients present with more advanced cancers than the population as a whole. The advanced stage of disease on presentation most likely results from a delay in the diagnosis and the low clinical suspicion of malignancy in this population. In a study, no patients were Duke stage A, 41% were stage B, 44% stage

C, and 15% stage D. In addition, most colorectal cancers are not diagnosed until late in pregnancy (> 20 weeks) or at the time of delivery.¹⁶⁴ Pregnancy could cause rapid tumor growth and progression of disease. There is a wide variation in the presence and expression of estrogen and progesterone receptors in colorectal tumors and, therefore, their biologic significance is unknown.^{167,168} Colonic malignancy during gestation most likely represents pregnancy superimposed on colon cancer rather than a pregnancy-related disease.

Diagnosis

The most frequent symptoms of colorectal cancer are abdominal pain, distention, nausea and vomiting, constipation, and rectal bleeding. The diagnosis may be delayed because many of the symptoms are common in pregnancy. Certainly, when a pregnant patient presents with or without rectal bleeding and persistent signs or symptoms suggestive of colorectal disease, rectal examination, stool tests for occult blood, and flexible sigmoidoscopy or colonoscopy should be done. Complete colonoscopy, as indicated for the nonpregnant patient, is the procedure of choice to obtain a biopsy and confirm the diagnosis of colorectal cancer in pregnancy.¹⁶⁹ However, possible adverse effects of colonoscopy in pregnant women include placental abruption, fetal exposure to potential teratogenic medications, and fetal injury resulting from maternal hypoxia or hypotension.¹⁷⁰ If deemed necessary, both the patient and her family should be fully informed about the potential risks to the mother and the fetus, and informed consent should be obtained. Because most cancers are located below the peritoneal reflection, they can be easily accessed and sampled for biopsy through a limited sigmoidoscopic examination. Endoluminal ultrasonographic staging of rectal cancer is particularly useful during pregnancy because of its ability to evaluate invasion of the uterus or encroachment of the cervix that could prevent vaginal delivery.¹⁷¹ Serum carcinoembryonic antigen levels are normal or only marginally elevated in a normal pregnancy. Therefore, baseline values should be measured and followed and used in the same way as in the nonpregnant patient.^{172,173} Although abdominal CT for staging colon cancer in pregnancy is contraindicated, particularly in the first trimester, it can be performed later in pregnancy in more difficult and advanced cases. Alternatives include ultrasonography and MRI without contrast to assess the extent of the cancer in the abdomen and the pelvis. Ultrasonography has a sensitivity of 75% for detecting hepatic metastases.

Treatment

Treatment of colon cancer in pregnant women involves caring for both the patient and the fetus and requires a multidisciplinary approach, which may include but is not limited to the obstetrician–gynecologist, maternal–fetal medicine specialist, colorectal surgeon, medical oncologist, neonatologist, pharmacist, social worker, and psychological support services. Aside from the difficulty in dealing with a potentially lethal disease in a young person, there is an inherent conflict between the treatment of the mother and the fetus. Treatment of colon cancer puts the two at odds. The necessary treatment must balance oncologic outcomes with the effect on the pregnancy, and decisions regarding the management of pregnancy include termination, iatrogenic prematurity, or intentional delay in treatment. The decision-making process must also account for the wishes of the patient/family, tumor stage, gestational age, and the effects of the specific therapeutic option.¹⁷⁴ In addition, tumor complications such as bowel obstruction, perforation, or bleeding may force surgical intervention.¹⁷⁵ Although there are no universally accepted guidelines for the treatment of colorectal cancer in pregnancy, the general consensus is that if the patient is diagnosed at less than 20 weeks' gestation and there is no evidence of metastatic disease, surgical resection is indicated. Waiting months until adequate fetal maturation for delivery can allow cancer dissemination and disease progression.^{171,176} In most cases, a colon resection can be handled without disturbing the pregnancy, and resection of even low-lying tumors can be performed before 20 weeks of gestation.¹⁷⁷ During the first half of pregnancy, hysterectomy is not necessary to perform colon or rectal resection, and thus, therapeutic abortion is not mandated. However, because of the controversial data regarding the risks of such resections to the pregnancy, termination of pregnancy and resection of the tumor should be one of the discussed management options. After 20 weeks, resection may be delayed until after fetal viability.¹⁷⁸ Although abdominal procedures with appropriate fetal and maternal monitoring performed late in pregnancy are not associated with fetal loss, delaying surgery allows fetal maturity of facilitate surgical exposure and dissection. If the colorectal tumor causes obstruction in the first half of pregnancy, primary resection, with or without anastomoses, can be performed. Obstructing tumors discovered in the second half of pregnancy, depending on the size of the uterus, can be treated with primary resection or by proximal

diversion, followed by curative resection several weeks after delivery. The surgical management of the patient's ovaries is controversial. However, due to the high incidence of ovarian metastases in pregnant patients with colorectal cancer (25%), compared with a 3% to 8% incidence in the general population, as well as the poor prognosis of metastatic colorectal cancer in the ovaries, the general recommendation is for bilateral salpingo-oophorectomy at the time of primary tumor resection.¹⁷⁹⁻¹⁸¹ Nesbitt and coworkers¹⁷⁶ recommend performing bilateral ovarian wedge biopsies with frozen section, and the ovaries are removed only when there is metastatic ovarian disease or when hysterectomy is indicated for another reason. Adjuvant chemotherapy or radiation therapy can improve survival of the mother but is generally contraindicated during pregnancy, especially early in gestation. Adjuvant chemotherapy conveys a survival advantage to patients with Dukes stage C colon cancer. The classic adjuvant chemotherapy includes 5-fluorouracil, an antimetabolite that inhibits DNA synthesis. The safety of this drug during pregnancy is questionable, and evidence of fetal toxicity exists in animal models. Limited data on the human fetal safety of this drug are available, and it is considered a category D drug during pregnancy by the FDA. Chemotherapy during the first trimester is usually contraindicated and should be limited to those patients with Dukes stage C lesions who are willing to accept the risks of fetal teratogenesis or demise. Chemotherapy during the second and third trimesters is less teratogenic because of the completion of organogenesis but still carries some risk for the fetus.^{171,182} Adjuvant radiation therapy reduces the local recurrence of rectal cancer. Because the most effective dose to eradicate microscopic disease is on the order of 50 Gy and the fetus cannot be effectively shielded from pelvic exposure, radiation therapy cannot be safely performed during pregnancy. Therapeutic pelvic radiation also results in permanent and irreversible female sterility, so the mother considering this form of therapy must be fully aware of the risks to the current and future pregnancies.^{171,183} Vaginal delivery is not contraindicated unless the tumor is obstructing the birth canal or presents a risk of episiotomy entering the tumor bed. However, vaginal birth is usually avoided because lower rectal lesions may cause dystocia, or delivery may cause tumor hemorrhage. If a cesarean section is performed for obstetric reasons or because of tumor impingement on the birth canal, resection can be performed immediately, but the operation may be technically easier if done as a separate procedure and postponed for several days. This is especially important with low rectal lesions, in which decreased pelvic vasculature can facilitate a low anterior or abdominoperineal resection.¹⁷⁶ There is no evidence that pregnancy influences the course of colorectal cancer, and the prognosis appears to be similar than that for identical stages in nonpregnant patients.¹⁸⁴

SECTION O: SKIN AND SOFT TISSUE

Chapter 107

Cutaneous Neoplasms

Michael S. Sabel, Timothy M. Johnson, and Christopher K. Bichakjian

Key Points

- 1 Cutaneous neoplasms are the most commonly diagnosed malignant tumors in the United States.
 - 2 Risk factors for development of cutaneous melanoma include ultraviolet (UV) light exposure, fair complexion/inability to tan, blue or green eyes, blonde or red hair, freckling, history of actinic keratosis or nonmelanoma skin cancer (NMSC), history of blistering or peeling sunburns, immunosuppression, personal or family history of melanoma, *CDKN2A/p16/MC1R* mutation, xeroderma pigmentosa, atypical (dysplastic) nevus, more than 100 normal nevi, and giant congenital melanocytic nevus.
 - 3 The ABCD rule is used to assess skin lesions for melanoma risk: A is for *asymmetry*; B is *border* irregularity; C is *color*; and D is *difference*, or a change in a lesion.
 - 4 Melanoma prognosis is inversely correlated to tumor thickness; ulceration and increased mitotic rate are independent survival risk factors; and nodal tumor burden (uninvolved vs. microscopic vs. macroscopic disease) has an inverse correlation with survival.
 - 5 For melanoma in situ, excision margins of 0.5 to 1.0 cm are indicated; for invasive melanoma, wide excision of the primary tumor with margins generally ranging from 1 to 2 cm is indicated for local control.
 - 6 Clinically involved lymph nodes should be resected; patients with primary melanomas of 1-mm thickness or greater and clinically negative nodes should be considered for sentinel lymph node biopsy. Patients with primary melanoma 0.75- to 0.99-mm thickness should also be considered for sentinel lymph node biopsy if they have additional risk factors for nodal metastases.
 - 7 Basal cell and squamous cell skin carcinoma account for 96% of new NMSCs.
 - 8 Merkel cell carcinoma (MCC) is an aggressive cutaneous neuroendocrine carcinoma treated by a combination of surgery and radiation, which has a higher mortality than melanoma.
 - 9 Dermatofibrosarcoma protuberans (DFSP) is a rare soft tissue sarcoma (1% of all soft tissue sarcomas) with a propensity for local recurrence rather than systemic metastasis.
-

1 Cutaneous neoplasms are the most commonly diagnosed malignant tumors in the United States, with an incidence of approximately 1.4 million new cases annually.^{1,2} One in five Americans (one in three Caucasians) born today will be diagnosed with skin cancer in their lifetime. More than half of all cancers diagnosed in the United States are skin cancers. The most common skin cancer types are basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). Cutaneous melanoma accounts for <2% of skin cancer diagnoses but the vast majority of skin cancer deaths, with 9,940 deaths due to melanoma in 2015. One person dies of melanoma every hour. Approximately 73,870 new cases of invasive melanoma (42,670 men and 31,200 women) were diagnosed in the United States in 2015. The incidence of melanoma has dramatically increased, with the lifetime risk of melanoma increasing from 1 in 600 in the 1960s to 1 in 50 in 2015. Of the seven most common cancers in the United States, melanoma is the only one whose incidence is increasing. Invasive melanoma is the fifth most common cancer in men and the seventh most common cancer in women.¹ The early diagnosis and surgical treatment of these skin cancers can be curative.

MELANOMA

Etiology and Risk Factors

- 2 Numerous environmental and genetic risk factors have been implicated in the development of

cutaneous melanoma, many of which center around sun exposure.³ Risk factors include factors related to exposure to UVA and UVB, such as geography, occupation, a history of blistering or peeling sunburns, and the use of tanning beds/salons, as well as factors related to increased sensitivity to UV light, such as decreased pigmentation, a fair complexion (blue or green eyes, blonde hair, freckling), or xeroderma pigmentosa. Melanoma incidence is subject to large geographic and ethnic variations, mainly because of an inverse correlation with latitude and with degree of skin pigmentation. Populations residing closer to the equator have a higher incidence of melanoma. Many factors that increase risk for melanoma are surrogates for a history of excess sun exposure, such as actinic keratosis, a history of either melanoma or an NMSC, atypical nevi, or multiple normal nevi. Finally, there are inheritable risk factors, such as a family history of melanoma, *CDKN2A/p16* mutation, or *MC1R* mutation.

Adults with more than 100 clinically normal-appearing nevi, children with more than 50 clinically normal-appearing nevi, and any patient with atypical or dysplastic nevi are at risk. A prior history of melanoma places a patient at increased risk, with 5% to 10% of individuals developing a second primary melanoma. This risk of developing a second primary is lifelong and can occur anywhere on the skin. Therefore, long-term surveillance with a thorough total body examination is recommended.

A genetic component has been implicated in the pathogenesis of melanoma. Of patients with melanoma, 10% to 15% report a positive family history. The most common chromosomal mutation associated with melanoma involves *CDKN2A*, also known as *p16*. However, the mutation accounts for only a small percentage of melanoma cases observed, estimated at 0.2%. An *MC1R* gene mutation is clearly a risk factor for cutaneous melanoma.⁴ The combination of *MC1R* mutation and red hair is associated with a very high risk of melanoma development. In addition, *MC1R R151 C* modifies the effect of another cutaneous melanoma susceptibility gene, *CDKN2A*.⁴ The genetic etiology of melanoma represents an area of future discovery.

The hereditary nature of cutaneous melanoma was also noted in the 1970s.⁵ Members afflicted with the “B-K mole syndrome,” named after two families, acquired large, irregular, and dysplastic nevi, often in sun-protected regions of the body such as the scalp and trunk. During this time period, Lynch et al.⁶ independently reported a familial association of melanoma among individuals with atypical nevi, which he termed *familial atypical multiple mole melanoma syndrome*, or FAMMM syndrome, with an autosomal dominant inheritance pattern. The 10-year melanoma risk in the setting of atypical mole syndrome is reported to be 10.7% compared with 0.62% in control patients. Greene et al.⁷ approximated a 56% cumulative risk from the age of 20 to 59 years, with 100% of patients with atypical mole syndrome developing melanoma by the age of 76 years. An atypical nevus is not a premelanoma but represents a genetic marker for increased risk of development of melanoma, which may occur anywhere on the skin surface including sun-protected sites. In fact, more than 50% to 75% of melanomas develop on clinically normal skin *de novo*, not in pre-existing melanocytic lesions.

Xeroderma pigmentosa is a rare autosomal recessive disorder associated with a reduced or absent ability to repair DNA damaged by UV light. Consequently, this disorder results in the development of multiple primary cutaneous malignancies, including melanoma as well as BCC and SCC. Individuals are usually diagnosed with their first cancer before the age of 10 years. Unfortunately, the development of skin cancers is relentless.

Congenital melanocytic nevi (CMN) are present at birth or appear within the first 6 months of infancy.⁸ An estimated 1% to 6% of children are born with CMN. The nevi are classified by size. Small CMN measure less than 1.5 cm in diameter and account for the majority of lesions. Medium CMN measure between 1.5 and 19.9 cm in diameter. Large CMN, also termed *giant congenital nevi*, measure 20 cm or greater. This large size can lead to significant cosmetic and psychosocial implications. The risk of melanoma development in small- and medium-sized CMN is similar to any other area of skin. Melanoma development in small and medium CMN usually occurs after childhood and arises from the dermoepidermal junction, making early detection feasible. Routine prophylactic removal of small and medium CMN is rarely indicated in the absence of signs or symptoms for malignant progression. Conversely, giant congenital nevi carry an increased risk for melanoma, with an estimated rate of 5% to 20%. Of giant congenital nevi that progress to melanoma, 70% are diagnosed prior to the age of 10 years. Melanoma can originate deep in the epidermis in giant congenital nevi. Consequently, diagnosis within the setting of giant congenital nevi is challenging and may develop deep in the skin with a more advanced primary lesion.

Patients with a giant congenital nevus, especially on the posterior axis, or in conjunction with many satellite lesions are also at risk for neurocutaneous melanocytosis (NCM).^{9,10} NCM is characterized by the presence of benign or malignant leptomeningeal tumors. Most patients present in the first 2 years of

life with neurologic manifestations of increased intracranial pressure, mass lesions, or malignant transformation to melanoma. Magnetic resonance imaging (MRI) findings of NCM may be present, even in asymptomatic children. NCM is associated with an increased risk of development of central nervous system melanoma. Symptomatic NCM is associated with a poor prognosis, even in the absence of malignancy. Chemotherapy is not effective, but shunt placement to reduce intracranial pressure may be palliative.

Clinical Diagnosis and Classification

3 Melanoma may have a characteristic appearance (Fig. 107-1). Early detection is key. The ABCD rule, which outlines the warning signs of melanoma, was developed decades ago.¹¹ A stands for *asymmetry* – one-half of the lesion does not match the other half when drawing an imaginary line through the center of the lesion. B is *border irregularity* – the edges of the lesion are ragged, notched, or fuzzy. C is *color* – the pigmentation is not uniform throughout the lesion. Varying shades of tan, dark brown to black, or shades of red, white, and/or blue may be present with a mottled appearance. While historically D has been used for *diameter* (a width greater than 6 mm, or the size of a pencil eraser), today many use *difference* – any change in the lesion. Alternatively, some maintain D as *difference* and add E for *evolution*. The seven-point checklist used in Europe incorporates several of the ABCD features, including change. Another useful diagnostic aid is the “ugly duckling” sign. A pigmented lesion that is different from the others should be carefully approached with a high index of suspicion.

The goal of any diagnostic aid is early detection and the ability to differentiate between benign and malignant, with 100% sensitivity combined with high specificity. The ABCD (or ABCDE) rule, seven-point checklist, and ugly duckling sign all provide relatively high sensitivity but none fulfills all of these criteria, especially with respect to specificity, to distinguish melanoma from benign lesions.

The ABCD criteria may fail to detect an important subset of nodular melanoma (NM), which often does not exhibit the ABCDs and is often less than 6 mm in early development. The ABCD rule is also relatively static without the important critical characteristic of change. Studies have documented early signs of a change in size, shape, or color and the early symptom of persistent itching. One of the best tools for diagnosis of early lesions that may fail to exhibit many of the standard melanoma features is the importance of *change*, hence the reason the authors and others have used the D in the ABCD rule to signify “*difference*.” A difference or change in lesions, especially with respect to size, shape, color, or persistent itching, warrants evaluation. Furthermore, the nevi on the body should globally share a common look or family resemblance. If one of the nevi seems different from the rest, it should be evaluated with a high index of suspicion. In addition, if all of the nevi are atypical or irregular but are morphologically similar to one another and are not changing, there may be no reason for individual lesion concern (atypical or dysplastic nevi). However, the presence of atypical nevi represents a risk factor for melanoma development anywhere on the skin surface with development in clinically normal skin, normal nevi, and dysplastic nevi with relatively equal frequency. Thus, excision of all atypical nevi does little for prevention. Education of the patient for early signs and symptoms, particularly change or difference, is key in this clinical scenario.

It must be emphasized that critical diagnostic decisions concerning skin lesions should still always be based on clinical assessments and the history, with attention to melanoma risk factors. The optimum diagnostic aid that combines 100% sensitivity and specificity currently does not exist. The use of all available means, including the ABCD and seven-point checklists, ugly duckling sign, difference, photography, dermoscopy, and evolving digital and computer-assisted imaging technologies, enhances the ability to diagnose melanoma at the earliest stage.¹¹ The result of using these multiple diagnostic aids is earlier detection of melanoma with higher overall survival rates.

Based on histologic patterns and clinical characteristics, melanomas can be classified into multiple categories, with the four major subtypes being lentigo maligna melanoma (LMM), superficial spreading melanoma (SSM), NM, and acral lentiginous melanoma (ALM).¹² In general, these subtypes derive their prognostic biologic behavior and risk of metastasis based on a secondary correlation with Breslow depth and are thus not independent prognostic factors. Invasive LMM constitutes 10% to 15% of cutaneous melanomas and typically occurs on the chronically sun-exposed areas of the head and neck, most often in older individuals. Clinically, the LMM pattern is associated with a significantly higher rate of often extensive and asymmetrical subclinical growth several centimeters beyond the clinical lesion. Failure to completely excise the entire lesion with meticulous margin control results in higher recurrence rates with lethal potential. In addition, amelanotic and desmoplastic melanoma with neurotropism is more frequent in the lentigo maligna (LM) lesion subtype. LM is not a benign disease as once thought. LM

represents in situ melanoma and, with time, progresses to invasive LMM. LMM often begins as a flat brown lesion on chronically sun-exposed areas with progression to black and other classic melanoma features over time.

Figure 107-1. Examples of skin lesions. A: Giant congenital nevus. B: Lentigo maligna (Hutchinson freckle). C: Melanoma arising in a lentigo maligna (lentigo maligna melanoma). D: Superficial spreading melanoma. E: Nodular melanoma. F: Acral lentiginous melanoma (ulcerated nodular plantar melanoma with satellite lesions). G: Subungual melanoma. H: Pigmented basal cell carcinoma.

SSM accounts for approximately 70% of cutaneous melanomas. This pattern is the most common in melanomas arising in a pre-existing nevus. SSM is typically characterized by variation in color, irregular borders, and irregular surface and often exhibits the classic melanoma clinical features.

NM occurs in approximately 15% to 30% of patients with cutaneous melanoma and is often the most aggressive of the four types of melanoma because of later detection and rapid growth. In general, NM may be more uniform in coloration than the other types, have regular borders with size less than 6 mm in early lesions, and lack the classic melanoma features initially. A change in a lesion is important for early detection.

ALM is a distinct clinicopathologic variant of melanoma that most commonly occurs on the hands, feet, fingers, and toes as well as in subungual locations ([Fig. 107-1](#)). ALM represents only 2% to 8% of melanoma in whites but 35% to 60% in people of color. Later detection frequently occurs because of location that is not easily or routinely examined and a low index of suspicion. When corrected for Breslow depth, the overall prognosis for ALM appears similar to the other subtype categories. In subungual locations, ALM can appear as an irregular, tan-brown streak in the nail that originates from the base of the nail bed. More than three fourths of subungual melanomas involve the great toe or thumb, and they can be confused with subungual hematoma.

Other rare melanoma subtypes deserve brief mention. Mucosal, anal, and vulvovaginal melanomas are associated with a poorer prognosis, possibly related to advanced disease at presentation with late detection and high vascularity at the lesion site. Desmoplastic melanoma is associated with a higher rate of neurotropism and lower rate of lymph node metastases.¹³⁻¹⁵ Small cell or nevoid melanoma often lacks any of the classic features, is difficult to accurately diagnose without expert dermatopathology interpretation, and thus may be initially more frequently misdiagnosed. And, amelanotic melanoma, occurring in 3% to 4% of cases, is often associated with late detection due to lack of pigment and failure to diagnose early.

Staging and Prognostic Factors

4 A great deal of information is available regarding various factors that correlate with the clinical outcome of patients with melanoma. Some of these prognostic factors, such as microstaging and nodal status, are of sufficient independent significance to be incorporated into staging systems with known survival rates. Other prognostic factors such as tumor ulceration and microscopic versus macroscopic nodal disease have also been found to be significant variables that influence survival and have been incorporated into the staging system.

Microstaging

One of the most important prognostic features of cutaneous melanoma is the stage of development of the primary tumor. The microstaging method that is used routinely was originally described by Breslow.¹⁶ This method classifies the primary tumor according to its thickness in millimeters, as measured with an ocular micrometer, from the top of the granular layer to the base of the tumor. Many investigators have documented an inverse correlation between tumor thickness and survival. The largest series of 17,600 patients reported by Balch et al.¹⁷ is summarized in Table 107-1. The ulceration status and mitotic rate are also independent factors that are used to determine microstaging of the primary lesion.^{17,18} Prior to the use of the Breslow microstaging method, melanomas were staged according to the level of invasion into the histologic layer of skin. This was known as the Clark level of invasion and comprised five levels (I, in situ lesions; V, subcutaneous involvement). Several studies have confirmed that Breslow thickness conveys more accurate prognostic information than does the determination of Clark level.^{17,19}

The presence of regional lymph node metastases is associated with a worsening prognosis. The tumor burden (microscopic vs. macroscopic disease) of involved lymph nodes has an inverse correlation with long-term survival.^{17,19} The 5-year survival rate for patients with involved lymph nodes ranges from 70% to 25%, based primarily on tumor burden and ulceration status of the primary lesion (Table 107-1). The use of sentinel lymph node biopsy (SLNB) has identified a subgroup of patients with micrometastatic nodal disease who have a favorable prognosis compared with patients with macroscopic nodal involvement. This information has been incorporated in the staging system as well.

RESULTS

From Balch CM, Gershenwald JE, Soong S-J, et al. Final version of 2009 AJCC melanoma staging and classification. *J Clin Oncol* 2009;27:6199–6206. Reprinted with permission from the American Society of Clinical Oncology.

Clinical and Pathologic Staging

The American Joint Committee on Cancer (AJCC) developed a five-stage system that divides melanomas according to tumor thickness (T), nodal status (N), and metastatic disease (M).^{17,19} The

current system was updated in 2009 and is summarized in [Tables 107-2](#) and [107-3](#). There are five stages based on prognosis: stage 0 (in situ melanoma), stage I (local disease), stage II (local disease), stage III (regional nodal, in-transit, or satellite metastases), and stage IV (distant metastases).

Other Prognostic Factors

The major prognostic factors that predict survival in melanoma patients have been accounted for in the AJCC staging system – namely, tumor microstaging, ulceration, nodal status, and distant metastases.^{17,19} The presence of ulceration in a melanoma appears to be associated with a poorer prognosis. Men have a higher proportion of ulcerated lesions than women (27% vs. 19%, respectively). Although ulceration appears to correlate with thickness of the melanoma, the presence of ulceration is an independent prognostic factor and has been included in the staging system.^{17,19} In addition, a higher mitotic rate of 1.0 mm² or greater is an independent prognostic factor of both nodal involvement and survival.^{18,20–22} The presence of angiolymphatic invasion is also a poor prognostic sign.

Treatment of Primary Melanoma

Biopsy

For localized melanoma, the tumor thickness (Breslow depth of invasion) is the single variable that most accurately determines therapy and prognosis. The ulceration status and mitotic rate also represent independent prognostic variables. A full-thickness biopsy with 1- to 2-mm margins only, to the adipose tissue, is preferred for any lesion highly suspect for melanoma.²³ If the melanoma is transected with a partial-thickness shave biopsy, the ability to obtain an accurate measurement of tumor thickness is lost. Therefore, a superficial shave biopsy is never recommended for a suspect pigmented lesion. Saucerization, which uses a curved blade to perform a deeper shave biopsy down to the subcutaneous fat, is acceptable.

Excisional biopsy with 1- to 2-mm margins is the preferred method for suspect lesions to provide the pathologist a total specimen for histologic interpretation and accurate microstaging. Performing a wide excision as the first step, especially on the trunk or head and neck, is not recommended, as several benign and malignant lesions can mimic melanoma and because doing so may result in the inability to accurately perform SLNB. Formalin-fixed, paraffin-embedded, permanent sections should be used for biopsy diagnosis of primary cutaneous melanoma to accurately determine tumor thickness and other histopathologic prognostic variables. Frozen sections have no role in the diagnosis or microstaging of primary melanoma. If the lesion is a melanoma, the excisional biopsy represents the first stage of a two-stage procedure. The second stage is reexcision with margins generally ranging from 0.5 to 2.0 cm, with or without SLNB, depending primarily on the tumor thickness. When biopsying a suspected melanoma on the extremities, it is critical that the biopsy be oriented on the long axis of the extremity, parallel to the lymphatics. Performing a biopsy oriented transversely on the extremity may not only compromise the accuracy of lymphatic mapping but may also obligate the patient to a skin graft to close the subsequent wide excision defect.

For suspicious lesions that are too large for complete excision and those that are located where the amount of skin is critical in terms of functional or cosmetic results, an incisional biopsy may be performed with an elliptical incision, deep saucerization shave to adipose or deep dermis in thick skin areas, or a punch biopsy. Incisional biopsies for melanoma do not increase the risk of local recurrence and distant metastasis or affect patient survival. They should generally be performed on the most raised or most pigmented area of the lesion to maximize the obtainable diagnostic and prognostic information. The most raised area usually corresponds to the maximal thickness of the lesion, but not always. Several incisional biopsies can be obtained from different areas for large lesions with multiple morphologic features. In the scenario of incisional biopsy with significant remaining lesion, complete excision for accurate microstaging should be considered prior to definitive treatment, unless the lesion is already 1 mm or greater in Breslow depth.

Metastatic Workup

In an attempt to standardize staging workup for melanoma, the National Comprehensive Cancer Network (NCCN) has published guidelines.²⁴ There are three basic reasons to perform a metastatic workup following the diagnosis of primary cutaneous melanoma: (a) for staging and prognosis, (b) to detect an early metastasis with potential survival benefit, and (c) to avoid morbidity of an extensive surgical procedure by detection of a distant metastasis.²⁴ The best test for the staging workup still starts

with a history (a focused review concentrating on constitutional, respiratory, neurologic, hepatic, musculoskeletal, gastrointestinal, skin, and lymphatic systems) and physical examination (total body skin examination, palpation of lymph nodes). Routine imaging (chest x-ray, computed tomography [CT] scans, positron emission tomography [PET] scans) and blood studies (complete blood cell count, comprehensive metabolic profile, liver function tests, serum lactate dehydrogenase [LDH] levels) in asymptomatic, clinically node-negative patients are low in both sensitivity and specificity and are not necessary.²⁵⁻²⁸ False-positive staging tests are common and lead to more tests and patient distress. SLNB represents the best baseline staging test, with both relatively high sensitivity and specificity in patients at significant risk for metastasis. The ability to detect stage IV disease with routine studies is small if the SLNB is negative. Both ultrasound and PET scanning have been examined as methods of identifying nodal metastases prior to surgery. While they detect disease in a minority of patients, the sizes of most metastases to the regional nodes are below the threshold of ultrasound or PET to detect, so this is not a cost-effective strategy.²⁹⁻³¹ If a thorough history and physical and detailed review of systems reveal no signs or symptoms suspicious for regional or distant disease, then no further staging is necessary. However, a high index of suspicion should be maintained and a thorough symptom-directed workup should be initiated for any worrisome finding on the history and physical.

STAGING

Table 107-2 American Joint Commission on Cancer Melanoma Staging System, TNM Definitions

Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Melanoma in situ
T1	≤1-mm Breslow thickness a. Without ulceration and mitosis <1 mm ² b. With ulceration or mitosis ≥1 mm ²
T2	1.01–2.00 mm a. Without ulceration b. With ulceration
T3	2.01–4.00 mm a. Without ulceration b. With ulceration
T4	>4 mm a. Without ulceration b. With ulceration
Regional Lymph Node Involvement	
NX	Nodal status cannot be assessed.
N0	No regional node metastasis
N1	Metastasis in 1 regional node a. Micrometastasis (diagnosed by SLNB or elective lymph node dissection) b. Macrometastasis (clinically palpable or found on imaging studies, confirmed histologically, or gross extracapsular extension)
N2	Metastasis in 2–3 regional nodes a. Micrometastasis b. Macrometastasis c. In-transit or satellite metastasis without metastatic nodes
N3	Metastasis in ≥4 regional nodes, matted nodes, or in-transit or satellite metastasis with positive metastatic nodes
Distant Metastasis	
MX	Cannot be assessed
M0	No distant metastasis
M1a	Distant skin, subcutaneous, or lymph node metastasis with normal LDH
M1b	Lung metastasis with normal LDH
M1c	All other visceral metastases with a normal LDH or any distant metastases with an elevated LDH

LDH, lactate dehydrogenase; SLNB, sentinel lymph node biopsy.

Approximately 5% to 10% of newly diagnosed melanoma patients present with clinically involved lymph nodes. Any clinically suspicious node should be confirmed by fine needle aspiration (FNA) biopsy, as enlarged lymph nodes may be reactive (particularly after a biopsy). Ultrasound-guided FNA biopsy can be useful in cases where the suspicious node is difficult to biopsy by hand. Patients documented to have macroscopic regional disease should undergo complete staging prior to definitive surgery, as a significant percentage may have more advanced regional or distant disease that may alter surgical therapy.^{32,33} Staging should include a serum LDH level; MRI of the head and either CT scan of the chest, abdomen, and pelvis; PET scan; or combined CT/PET scan. For patients with involved groin nodes, CT scan is recommended to visualize the pelvic nodes, as this may help determine the extent of inguinal node dissection.

^aClinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastasis. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

^bPathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.

^cThere are no stage III subgroups for clinical staging.

Surgical Excision of Primary Melanoma

5 The primary purpose of a melanoma excision is to prevent local recurrence due to persistent disease. For melanoma in situ, excision margins of 0.5 to 1.0 cm are indicated. For invasive melanoma, wide excision of the primary tumor, with margins generally ranging from 1 to 2 cm, is indicated for local control. The optimal margin width remains somewhat controversial. The historical approach of excising all primary melanomas with a 3- to 5-cm margin is extinct. At least five randomized controlled trials failed to demonstrate a difference in overall survival or local recurrence with narrow (1- to 2-cm) versus wide (3- to 5-cm) margins (Table 107-4). Of note, one trial demonstrated an increased risk of locoregional recurrence with 1-cm versus 3-cm margins for melanoma more than 2 mm thick.³⁴ Based on these trials, current consensus guidelines recommend margins of 1 cm for melanomas 1 mm or less thick, 2 cm for melanomas greater than 2 mm thick, and 1 to 2 cm for melanomas 1 to 2 mm thick. For this last group, the size of the margins should be based on the anatomic location of the melanoma and the morbidity of excising 2 cm versus 1 cm, including the need for an advancement flap or skin graft

(Table 107-5). For several locations, such as melanomas on the head and neck, the maximum margins attainable are dictated by anatomic limitations. Most subungual invasive melanomas require amputation of the digit. Perianal melanomas should be treated by wide excision, as these achieve similar long-term results compared with more radical surgery.^{35,36} Abdominoperineal resection (APR) may be necessary for locally advanced disease or melanoma of the anal mucosa. A complete staging workup should be performed before proceeding with APR, as these patients have a very high rate of regional and distant disease.³⁷

RESULTS

Table 107-4 Randomized Controlled Trials: Narrow Versus Wide Excision Margins

Trial ^a	Subjects (No.)	Narrow Resection Margin (cm)	Wide Resection Margin (cm)	Tumor Thickness (mm)	Tumor Site	Median Length Follow-up (years)
French 2003	326	2	5	<2.1	T, E, H&N	10.0
Intergroup 1996	470	2	4	1.0–4.0	T, E	7.6
Swedish 2000	989	2	5	0.8–2.0	T, E	11.0
WHO 1991	612	1	3	<2.0	T, E	7.5
UK 2004	900	1	3	>2.0	T, E	5.0

E, extremity; H&N, head and neck; T, trunk; UK, United Kingdom; WHO, World Health Organization.
^aThere was no difference in any outcomes in the first four trials. UK 2004 showed increased locoregional recurrence but no difference in local or in-transit recurrence.

TREATMENT

Table 107-5 Recommended Surgical Margins for Melanoma Excision

Melanoma Thickness (mm)	Clinical Excision Margin (cm)
In situ	0.5–1.0
≤1.0	1.0
1.1–2.0	1.0–2.0
>2.0	2.0

Margins may need to be modified on the basis of anatomic considerations but still require histologic confirmation of tumorfree margins. For clinically ill-defined lentigo maligna/lentigo maligna melanoma, wider margins may be required for histologic confirmation of tumorfree margins.

For the clinically ill-defined LMM, histologic confirmation of negative margins is important, and it should be emphasized that these margin recommendations may not apply to in situ LM and invasive LMM on the head and neck.^{38,39} LM and LMM are often associated with extensive subclinical involvement to as much as several centimeters beyond the clinical component. Careful and complete margin control, including excision of the lesional trailing edge of atypical melanocytic hyperplasia, often beyond the standard margins, may be necessary for complete surgical resection of LM/LMM on the head and neck.

Treatment of Regional Metastatic Melanoma

Lymphadenectomy Results and Indications

6 Surgical excision of metastases to regional lymph nodes is potentially curative therapy. The 5-year survival rate for patients who undergo lymphadenectomy for clinically positive involved nodes (AJCC stage III) ranges from 25% to 70%. In addition, for those patients not cured by lymphadenectomy, resection can avoid potential pain associated with tumor enlargement, skin breakdown, and tumor necrosis (Fig. 107-2). Only 5% to 10% of patients who first present with the diagnosis of melanoma have clinical evidence of nodal metastases, approximately 85% to 90% have localized disease, and the remaining 5% have distant metastases. In less than 3% of patients, a diagnosis of melanoma is made in the absence of a definable primary lesion.⁴⁰ When patients present with isolated nodal disease from an unknown primary site (an occult primary melanoma), the results of lymphadenectomy are similar to or better than those for patients with known primary tumors.⁴¹ For patients with melanoma 1 mm thick or greater who present with clinically negative nodes, SLNB should be considered to determine whether therapeutic lymphadenectomy is indicated.⁴²

Figure 107-2. A patient with large melanoma axillary involvement with skin ulceration.

Sentinel Lymph Node Biopsy

Morton et al.⁴³ were the first to develop the concept of “sentinel lymph nodes” in the nodal basins draining cutaneous melanomas. They hypothesized that melanoma involvement of a nodal basin develops in an orderly fashion with metastasis to the sentinel lymph node as the first step in that process. With the intradermal injection of a blue dye, these investigators were able to identify sentinel lymph nodes 90% of the time. If the sentinel node was negative for melanoma, the remaining lymph nodes were also free of involvement in at least 96% of cases. These results have been confirmed by multiple other groups.^{44,45}

Two tracers are typically used for identifying the sentinel lymph nodes: a radiolabeled colloid solution, and a blue dye – either methylene blue or 1% isosulfan blue (Lymphazurin). Lymphazurin carries a risk of allergic reaction in 0.5% to 2.0% of patients, which can be life-threatening.⁴⁵ Methylene blue dye has an extremely low risk of allergic reaction, although this should be diluted as it can cause skin necrosis if not completely resected. One to 4 hours before surgery, a radiolabeled colloid solution is injected intradermally around the primary tumor site or excision site, taking care to avoid injecting directly into any residual tumor. Lymphoscintigraphy imaging is then performed, which is critical in that it can identify sentinel nodes outside the traditional nodal basin. The blue dye is injected intradermally in the operating room a few minutes before the procedure. Using a handheld gamma detector probe, the surgeon is able to identify the sentinel lymph node location through the skin, thereby limiting the incision necessary to find the node. Blue-stained lymphatics and lymph nodes can be directly visualized (Fig. 107-3). The combined use of the blue dye plus the radiolabeled colloid enables the detection of the sentinel node in 97.3% to 98.6%.⁴⁶ The technique of SLNB is most often performed in conjunction with the wide excision of the primary tumor. It can routinely be performed as an outpatient procedure.

Figure 107-3. Blue dye tracking up a lymphatic vessel to a blue-stained lymph node.

Once the sentinel lymph node is removed, it is processed by the pathologist by step sectioning the entire node into multiple sections for routine hematoxylin and eosin staining. This is done to examine for micrometastases that could be missed by bivalving the node and performing an examination of only one section. If serial sectioning and staining are negative for metastasis, then immunohistochemical staining for melanoma markers such as S-100, Melan-A, and HMB-45 is performed.⁴⁷ These stains can identify microscopic clusters of tumor cells that are hard or impossible to identify by hematoxylin and eosin staining. The thoroughness of assessing the sentinel lymph nodes for metastatic disease has resulted in much more accurate staging of patients. Micrometastases to lymph nodes have been incorporated in the current staging system as described earlier.

If the sentinel lymph node is positive for melanoma, then complete lymph node dissection (CLND) (Fig. 107-4) is indicated on the basis of potential survival and clinical benefit. The final results of the Multicenter Selective Lymphadenectomy Trial I (MSLT-I), which randomized patients to wide local excision (WLE) alone or WLE in combination with SLNB and CLND for a positive SLN, demonstrated that disease-free survival rates were significantly improved in the SLN group, compared with the observation group, for both patients with intermediate-thickness melanoma ($71.3 \pm 1.8\%$ vs. $64.7 \pm 2.3\%$; HR = 0.76, $P = 0.01$) and thick melanoma ($50.7 \pm 4.0\%$ vs. $40.5 \pm 4.7\%$; HR = 0.70, $P = 0.03$).⁴⁸ Although MSLT-I showed no benefit on overall survival, subset analysis showed that node positive patients discovered on SLN biopsy had a 10-year melanoma-specific survival of $62.1 \pm 4.8\%$ compared with $41.5 \pm 5.6\%$ for patients who recurred during observation. Even after factoring for false-negative sentinel nodes, this remained significant (HR = 0.67; 95% CI, 0.46 to 0.97; $P = 0.04$). Although this subset analysis has been questioned as being valid,^{49,50} latent-subgroup analysis showed a clear, significant benefit of sentinel node biopsy.⁴⁸

An unresolved question is whether every patient with a positive sentinel lymph node requires CLND. Several attempts to retrospectively identify clinical or histologic factors that may predict the absence or presence of disease within the nonsentinel nodes have not identified any absolute way to determine who requires additional surgery, although a combination of the Breslow depth and burden of disease within the sentinel lymph node seems promising.⁵¹⁻⁵⁴ In addition, retrospective studies of SLN-positive patients who did not undergo CLND appear to have similar outcomes to those who did.⁵⁵⁻⁵⁷ The Multicenter Selective Lymphadenectomy Trial-II (MSLT-2), which randomized patients with a positive sentinel lymph node to CLND or serial ultrasonography of the regional basin, has completed accrual and will provide more information regarding the benefit of CLND for sentinel lymph node-positive patients. Until that time, CLND for a positive sentinel lymph node remains the standard of care in the treatment of melanoma.

Figure 107-4. Technique of groin dissection.

For patients with primary melanoma equal to or greater than 1-mm thickness with clinically negative nodes, SLN biopsy is recommended.⁴² For patients with thin melanoma, SLN should not be performed routinely but can be considered for patients with melanoma Breslow depth of 0.76 to 0.99, particularly if they have other risk factors for regional micrometastases, including a mitotic rate of 1 mitosis/mm² or greater, extensive dermal regression > 1 mm, ulceration, angiolymphatic invasion, younger age, or a broadly transected or positive deep margin on shave biopsy.^{20,58,59} Reasons not to perform SLNB include significant medical comorbidities or the patient does not desire SLNB after an informed discussion.

Radiation therapy has also been utilized as an adjuvant to the resection of high-risk nodal metastases (extranodal extension, nodes greater than 3 to 4 cm in size, or multiple nodes). Several retrospective studies had suggested improved regional control rates when radiation was combined with surgery, particularly for cervical metastases. A large, prospective randomized trial from the Tasman Radiation Oncology Group randomized patients at high-risk of nodal relapse to adjuvant radiation versus observation. With a median follow-up of 40 months, the risk of relapse in the lymph-node field was reduced with radiation (HR = 0.56, 95% CI: 0.32 to 0.98; *P* = 0.041) but there was no significant difference in either relapse-free or overall survival.⁶⁰ Adjuvant radiation after lymph node dissection will increase the overall morbidity, but this depends on the basin being irradiated, with ilioinguinal Radiation therapy (RT) being more problematic than cervical or axillary RT.^{61,62} The decision to consider adjuvant radiation after completion node dissection should be individualized on the basis of the predicted risk of regional recurrence, expected survival, and associated toxicities.

Adjuvant Therapy

Although the prognosis for patients with early-stage cutaneous melanoma is quite good, fewer than 50% of patients with thick primaries (i.e., >4 mm) or regional node involvement are cured by surgery alone. The development of effective adjuvant therapy capable of increasing postsurgical survival in high-risk groups of patients has been a long-standing goal of clinicians. Unfortunately, numerous randomized trials evaluating systemic chemotherapeutic agents (most notably dacarbazine), nonspecific immunotherapy (such as Bacille Calmette–Guérin), and tumor-specific vaccines in the adjuvant setting have failed to demonstrate any impact on survival.^{63–67}

Interferon- α 2b (IFN- α 2b) has a variety of modulatory effects on the immune system that could enhance antitumor reactivity. In 1996, Kirkwood et al.⁶⁸ reported the results of the Eastern Cooperative

Oncology Group E1684 trial, which studied the effectiveness of high-dose IFN- α 2b to improve disease-free and overall survival rates of patients with stage IIB (>4 mm) or III disease after surgery. High-dose IFN- α 2b includes a 1-month induction phase (IV 20 MU/m² M-F) followed by 11 months of maintenance (SC 10 MU/m² 3 days/week). In this multi-institutional prospective randomized trial, 287 high-risk patients with deep primary (>4-mm) tumors or positive nodes were randomly assigned after surgery to either postoperative adjuvant treatment with IFN- α 2b or observation. IFN- α 2b therapy significantly increased median overall survival by 1 year and produced a 24% improvement in the 5-year overall survival rate (46% for IFN- α 2b patients vs. 37% for observation patients). On the basis of these results, the Food and Drug Administration (FDA) approved the use of adjuvant IFN- α 2b after surgical resection of stage IIB or III melanoma. Two large, prospective randomized trials followed. E1690 compared high-dose interferon with both observation and low-dose interferon. The effect of high-dose interferon on 5-year relapse-free survival was significant (44% vs. 35%, $P = 0.03$) but neither high-dose nor low-dose interferon had any significant impact on overall survival.⁶⁹ Elective node dissection was not mandated in E1690 (nor E1684), and many patients who had regional recurrences on observation subsequently received IFN- α salvage therapy, which may have impacted the overall survival analysis. The third trial, E1694, compared high-dose IFN to the GMK vaccine; the ganglioside GM2 coupled to kehole limpet hemocyanin and combined with the QS-21 adjuvant. The trial was stopped early when an advantage was seen for interferon in both relapse-free (HR = 1.47; $P = 0.001$) and overall (HR = 1.52; $P = 0.009$) survival.

Pegylated IFN- α 2b (peg-IFN), where the IFN molecule is bound to a polyethylene glycol moiety, allows for sustained absorption and a longer half-life. This regimen has an induction phase of peg-IFN SC 6 μ g/kg a week for 8 weeks followed by a maintenance dose of SC 3 μ g/kg a week for up to 5 years. In the European Organization for Research and Treatment of Cancer (EORTC) trial 18991 of peg-IFN versus observation in patients with resected stage III melanoma, peg-IFN was associated with an improved RFS (HR = 0.87; 95% CI, 0.76 to 1.00; $P = 0.05$), with no difference in overall survival.⁷⁰ In 2011, the FDA approved peg-IFN as an alternative to high-dose IFN in the adjuvant therapy of melanoma.

Biochemotherapy (BCT) combines chemotherapy and immunotherapy and has been examined in stage IV melanoma for many years.^{71,72} It was studied as a potential adjuvant therapy in the Southwest Oncology Group (SWOG) trial S008, which compared a 9-week BCT regimen composed of cisplatin, vinblastine, dacarbazine, interleukin-2 (IL-2), and IFN- α to high-dose interferon.⁷³ While there was a significant improvement in RFS compared with HDI (4.0 years vs. 1.9 years; $P = 0.029$), there was a higher rate of grade III/IV toxicity and no difference in overall survival (56% 5-year survival in both groups). The use of BCT may be considered for adjuvant therapy in stage IIIA–IIIC melanoma.

Treatment of In-Transit Disease

In-transit disease and satellitosis develop in 5% to 8% of patients with melanomas thicker than 1.5 mm.⁷⁴ These are classified as stage III disease but portend not only a poor prognosis but can be a challenge to treat. Treatment involves either local excision or ablation, or regional chemotherapy. Surgical excision is the optimal management when the number of lesions is small and complete excision is possible. Prior to proceeding with surgery, a complete staging workup for metastatic disease is recommended, as these patients often harbor distant disease. When surgery is not feasible, a number of intralesional therapies have been utilized: Bacille Calmette–Guérin, IL-2, granulocyte-macrophage colony stimulating factor (GM-CSF), and rose bengal. A new agent, talimogene laherparepvec (T-VEC), is an oncolytic immunotherapy derived from herpes simplex virus type-1. Injected intralesionally, T-VEC is designed to replicate in tumors and release GM-CSF to enhance systemic antitumor immune responses. In a randomized phase III trial, T-VEC demonstrated an improved durable response rate (16% vs. 2%; $P < 0.0001$) and a trend toward an improved overall survival.⁷⁵

When the in-transit disease is unresectable but limited to an extremity, regional administration of high-dose chemotherapy can be effective in controlling disease. Isolated limb perfusion (ILP) uses an extracorporeal membrane oxygenator (as is used with cardiac surgery) to deliver chemotherapy doses 15 to 25 times higher than can be obtained with systemic delivery. The surgeon isolates the vessels and uses a tourniquet to prevent systemic uptake of the agent(s). Using the bypass machine, the limb is perfused with hyperthermic (38°C to 40°C) chemotherapy solutions, most commonly melphalan. After 60 to 90 minutes of treatment, the drug is flushed from the circulation and systemic circulation is restored. Response rates between 80% and 90% are reported, with complete response rates between 40% and 65%.^{74,76–78} In some cases, these can be quite durable. Toxicities can range from mild

erythema and edema to epidermolysis, functional impairment, and in extremely rare cases a need for amputation.

Isolated limb infusion (ILI) is a minimally invasive alternative to ILP. Rather than surgical isolation of the vessels, percutaneous catheters are placed radiologically in the artery and vein and connected to an extracorporeal circuit incorporating a heating coil. A tourniquet is placed on the extremity, but because some systemic uptake is anticipated, lower doses of chemotherapeutic agents are used. Some studies have reported response rates equal to ILP, although others report slightly lower response rates.^{79–82} However, the role of both ILP and ILI is evolving as new systemic therapeutic options become available.

Treatment of Disseminated Melanoma

Evaluation for Metastatic Disease and Clinical Course

The follow-up evaluation for patients with AJCC stage I, II, or III melanoma who are rendered NED by surgery should include regular histories and physical examinations. The use of extensive and frequent radiographic studies and blood work in asymptomatic, clinically disease-free patients is rarely productive.²⁴ For AJCC stage IA to IIA, the NCCN recommends that patients should undergo a history and physical examination with emphasis on skin and nodal examinations every 6 to 12 months as clinically indicated. For AJCC stage IIB to IV NED, patients should undergo a history and physical examination every 3 to 6 months for 2 years, then every 3 to 12 months for 3 years, and then annually as clinically indicated. Imaging studies (CXR, CT, or PET/CT) can be considered every 3 to 12 months for the first 3 to 5 years on the basis of the conditional probability of recurrence at any point in time after the initial therapy.²⁴

Melanoma can disseminate to any organ. The most common sites of recurrence are skin, subcutaneous tissues, and distant lymph nodes, followed by visceral sites. Common visceral sites of metastasis, in order of decreasing occurrence, are the lung, liver, brain, bone, and gastrointestinal tract. Most patients who die with disseminated disease have multiple organ involvement. Frequently, the cause of death is respiratory failure or brain complications. Cure with any treatment is rare. However, over the past several years, there have been tremendous advances in the systemic therapy of melanoma. Whereas only several years ago there were only two FDA-approved therapies for the treatment of metastatic melanoma (dacarbazine and high-dose IL-2), there are now new targeted therapies and immune checkpoint regulators that have been approved for the treatment of advanced melanoma, with several new therapies and combinations in clinical trial. How to proceed in the management of advanced melanoma should be based on several factors, including the patient's medical condition and comorbidities, the potential for palliation, and the impact of treatment on quality of life.

Chemotherapy

Melanoma is responsive to few chemotherapeutic drugs. The most widely used single chemotherapeutic agents have been dacarbazine and its oral analogue temozolomide, with objective response rates of 5% to 12%.⁸³ Most responses are transient; only 1% to 2% of patients achieve a durable long-term response.⁸⁴ Attempts to improve upon these results using combination chemotherapy, or BCT (where chemotherapy is combined with IFN- α 2b $\pm$ IL-2), failed to significantly improve upon single-agent therapy alone.^{71,83–85}

High-Dose Interleukin-2

IL-2 is a cytokine secreted by antigen-activated helper T cells, initially discovered to be a T-cell growth factor but subsequently found to have many other immunologic effects, including an important role in the enhancement of immune responses. High-dose IL-2 (600,000 IU/kg every 8 hours for up to 14 doses) is associated with an objective response rate of 15% to 20%, with a small percentage of patients (around 5%) experiencing long-term, durable complete responses (Fig. 107-5).^{86–88} These results may be improved upon with the addition of vaccines.⁸⁹ However, IL-2 treatment requires inpatient intensive care, as toxicity is severe and can include hypotension, pulmonary edema, decreased renal function, respiratory insufficiency, and neurotoxicity.

BRAF and MEK Inhibitors

The MAP kinase pathway is a key pathway in melanoma pathogenesis, with nearly half of melanomas having constitutive activation due to mutations in the *BRAF* gene.⁹⁰ Activation of mitogen-activated

protein kinase (MAPK) signaling leads to unregulated cell proliferation. Vemurafenib and dabrafenib are targeted therapies that block the constitutively active mutant BRAF. Both have been associated with significant improvements in both progression-free and overall survival compared with dacarbazine.^{91,92} Common adverse effects include arthralgia, rash, fatigue, alopecia, and the development of cutaneous keratoacanthomas and SCCs. Patients treated with BRAF inhibition have dramatic responses, but unfortunately the survival benefit is limited because of the eventual development of resistance in most patients.

Figure 107-5. Basal cell carcinoma near the eye.

Trametinib is a small molecule inhibitor of MEK1/2, a downstream regulator of BRAF. As with BRAF inhibition, MEK inhibition with trametinib was associated with an improvement in both progression-free and overall survival compared with chemotherapy.⁹³ While MEK inhibition had no efficacy in patients who failed BRAF therapy, the combination of BRAF and MEK inhibition was associated with an improvement in objective response, median duration of response, and progression-free survival, compared with BRAF inhibition alone.^{94,95} In addition to delaying the development of resistance to MAPK pathway inhibition, combination therapy is also associated with fewer secondary cutaneous malignancies. The FDA granted accelerated approval to the combination of dabrafenib and trametinib for the treatment of patients with advanced melanoma with BRAF^{V600E/K} mutations.

Immune Checkpoint Regulators

For many years, the plethora of immunotherapy research has centered on the generation of an antitumor immune response, primarily through the use of vaccines and assorted adjuvants. However, immune checkpoint regulation, which augments existing, yet clinically insignificant, immune recognition, has rapidly emerged as an alternative and effective form of immunotherapy in melanoma.

Ipilimumab is a human IgG1 mAb that binds to the cytotoxic T-lymphocyte associated antigen-4 (CTLA-4) receptor. This receptor is found on regulatory T-cells and cytotoxic T-cells after they have been activated, with a primary role of inhibiting T-cell responses. Blocking the binding between CTLA-4 and B7 suppresses this inhibitory function (essentially cutting the brakes) and promotes continued T-cell activation. In a phase III trial of ipilimumab alone, ipilimumab with a gp100 vaccine, and the vaccine alone, there was a significant improvement in median overall survival with ipilimumab (10.1 months vs. 6.4 months, HR = 0.66, $P = 0.0026$).⁹⁶ In a meta-analysis of pooled data from several clinical trials, the 3-year overall survival rate was 22%, with many of them being durable as the rate of additional deaths between 3 and 10 years was relatively low.⁹⁷ Ipilimumab is associated with immune-related toxicities, specifically enterocolitis, hepatitis, endocrinopathies, and dermatitis. While these can be severe, they are reversible if recognized and treated early. Another anti-CTLA-4 antibody, tremelimumab, which has a longer half-life than ipilimumab and thus has a longer interval between doses, is presently being studied.⁹⁸

Activated CD4⁺ and CD8⁺ T cells also express the programmed death 1 (PD-1) receptor, which, once bound to its ligand PD-L1, triggers a decrease in T-cell proliferation, IL-2 release, and T-cell survival. Malignant cells often express PD-L1 that binds to the receptors and blocks T-cell killing. Pembrolizumab

and nivolumab are monoclonal antibodies against PD-1 that prevent binding to PD-L1. Both have shown response rates in the 25% to 30% range, primarily in patients who have already progressed on or after treatment with ipilimumab.^{99,100} They were both approved by the FDA for second-line treatment, after treatment with ipilimumab. As with anti-CTLA-4, anti-PD-1 can be associated with immune-mediated toxicities, including colitis, endocrinopathies, and pneumonitis. In a phase III randomized trial comparing nivolumab with dacarbazine,¹⁰¹ in previously untreated patients, nivolumab was associated with a significant improvement in overall survival (72.9%, 95% CI: 65.5 to 78.9 vs. 42.1%, 95% CI: 33.0 to 50.9, HR = 0.42, $P < 0.001$) compared with chemotherapy, leading to a shift toward anti-PD-1 therapy as first-line therapy in advanced melanoma. In addition, early studies of combination therapy with anti-PD-1 and anti-CTLA-4 mAb have demonstrated improved outcomes with increased but manageable toxicity.¹⁰²⁻¹⁰⁴

Surgery

For most cancers, surgery is rarely considered as a curative option in stage IV disease. Historically, melanoma has been an exception to this, with documented long-term survival among patients who undergo resection of metastatic lesions. Several retrospective studies, as well as prospective studies, have suggested that metastasectomy may result in prolonged disease-free survival in select patients.¹⁰⁵⁻¹⁰⁹ The rationale for surgical extirpation of metastatic disease was in part driven by the lack of effective systemic therapies in melanoma. The role of surgery for stage IV disease is rapidly evolving as new, highly effective therapies have emerged. Despite the excitement surrounding these new agents, there may be potential advantages to metastasectomy in select patients, including cost, toxicity, time to palliation, and disease-free survival.¹⁰⁸ Careful patient selection is key, as is a true multidisciplinary approach. Patients being considered for metastasectomy should undergo a thorough search for additional sites of disease, including a detailed history and physical, serum LDH, CT or PET scan, and MRI of the brain. Biopsies should be obtained to document metastases as well as evaluate BRAF, and in some cases c-kit mutation status, as well as PD-L1 expression. Factors to consider when formulating a treatment plan include the age and health of the patient, the number and locations of the metastases as well as the ability to achieve negative margins, the morbidity of the operation, the disease-free interval between the original diagnosis and the development of distant disease, the need for palliation, either now or in the near future, and the available systemic options. For select patients, surgery may be considered as a first-line therapy, potentially delaying the need for systemic therapies, or be used in conjunction with systemic therapies, either after neoadjuvant therapy or for resection of lesions that fail to respond. The successful incorporation of surgery in the management of stage IV disease is dependent upon true multidisciplinary collaboration between surgical, medical, and radiation oncology.

NONMELANOMA SKIN TUMORS

7 BCC and SCC account for 96% of new NMSCs.^{1,2} These tumors are derived from epithelial origin. The ratio of BCC to SCC is approximately 4:1. The annual incidence of BCC and SCC in the United States alone exceeds 1 million cases. The public health burden on the US population from NMSC, for which the incidence is rapidly rising, is highly significant. Patients with NMSC have an excellent prognosis, with 90% to 99% curable with appropriate treatment and less than 1% resulting in death. SCCs account for 75% of NMSC deaths, which are estimated at 2,000 to 2,500 per year.¹¹⁰

Etiology

Both BCC and SCC are most commonly induced by significant exposure to UV light from the sun or tanning booths.³ These cancers are the predominant neoplasms of the head, neck, trunk, lower legs, and extensor arms and hands where sun exposure is common. Skin cancer is a significant occupational hazard for people who work outdoors. The phenotype at increased risk is one with fair skin who sunburns and freckles easily, has blue eyes, and has red or blonde hair. Melanin pigment in the skin appears to be the protective factor.

A number of genetic syndromes are associated with an increased risk of developing NMSC, including Gorlin syndrome, xeroderma pigmentosa, and albinism. Gorlin syndrome is an autosomal dominant disorder associated with multiple BCCs, palmoplantar pits, jaw cysts, frontal bossing, and hypertelorism. Albinism is a disorder characterized by a partial or complete deficiency in melanin production and, thus, loss of protective pigment. Another factor associated with NMSC, primarily SCC,

is chronic exposure to chemicals such as arsenic and hydrocarbons (found in coal tars, soot, and asphalt). Cigarette smoking has been associated with SCC of the lip and mouth. Human papillomavirus has been associated with cutaneous SCC in the genital and acral/periungual areas. Radiation has been associated with both SCC and BCC.

Basal Cell Carcinoma

BCC is the most common form of skin cancer. These epithelial-derived tumors can be divided into various subtypes according to clinical appearance, histologic pattern, and biologic behavior. Although BCCs rarely metastasize, they are characterized by slow but relentless and destructive local invasion that results in high morbidity without treatment. The subclinical local invasion may be deep, extensive, and asymmetric, with fingerlike extensions several centimeters beyond the clinical borders.

The most common subtype of BCC is the well-circumscribed nodular variety. These tumors often present as pearly papules or nodules with telangiectases. They may be pruritic and bleed occasionally. With time, the center ulcerates to create peripheral “rolled” borders; such ulcerating BCCs are called *rodent ulcers* (Fig. 107-5). Occasionally, the lesions are deeply pigmented and nodular and can be confused with melanoma. This variant has been called *pigmented BCC* (Fig. 107-1H). The histologic features of these tumors demonstrate isolated areas of basaloid tumor islands arising from the epidermis with peripheral palisading of nuclei and stromal retraction. In some cases, the BCC has histologic features of squamous metaplasia with keratinization. These tumors have basosquamous differentiation and can become more aggressive and develop regional lymphatic spread.

The most locally aggressive type of BCC is characterized by a diagnostic histopathologic aggressive growth pattern, known as morpheaform, sclerosing, or fibrosing BCC (Fig. 107-6). Clinically, these tumors may be more subclinical, are flat, and appear to be scarlike. They have a significant incidence of recurrence because of the isolated, fingerlike fronds of basal cell tumor cells that may deeply invade the surrounding structures well beyond the clinical margins of the lesion. These small, fingerlike islands are often missed with standard histologic margin control.

Clinically, superficial BCCs are scaly pink to red lesions. Frequently, they are confused with psoriasis or other eczematous, scaly dermatoses. Although these tumors are usually relatively superficial, extensive superficial subclinical involvement is common. Numerous risk factors are associated with possible extensive subclinical invasion and increased rates of local recurrence for BCC after standard treatment, including surgical excision (Table 107-6).

Figure 107-6. Morpheaform basal cell carcinoma of the scalp.

Squamous Cell Carcinoma

SCC is the second most common form of skin cancer and is derived from the epithelial keratinocyte. SCC can deeply invade surrounding structures and metastasizes most commonly to regional lymph nodes. In immunosuppressed transplant individuals, SCC is the most common skin cancer, occurring 65 to 250 times more frequently than in the general population. SCC in these individuals tends to have more aggressive behavior.

Several precursor lesions to invasive SCC exist, most commonly actinic keratoses and Bowen disease (in situ SCC). Erythroplasia of Queyrat, another precursor lesion, represents SCC in situ on the glans

penis. Histologically, SCC shows malignant degeneration of epithelial cells with differentiation toward keratin formation. SCC often appears clinically as a nonhealing sore with ulceration and inflammatory pink borders or an erythematous papulonodule with overlying keratotic crust or ulceration (Figs. 107-7 and 107-8). These tumors most often arise in chronically actinically damaged skin or within an actinic keratosis, but they may also develop in burn scars or chronic inflammatory wounds. These lesions may infiltrate widely. Metastasis to regional lymph nodes accounts for approximately 80% to 90% of metastatic cases. Distant sites, such as the lung, liver, brain, bone, and skin, account for the other 10% to 20%. Metastatic SCC portends a poor prognosis with a 10-year survival rate for regional lymph node disease of less than 20% and for distant disease of 10%.

Table 107-6 Basal Cell Carcinoma: Higher-Risk Factors for Subclinical Invasion and Recurrence

■ Recurrent tumor
■ Anatomic location <i>High risk:</i> Central face, eyelid, eyebrow, periorbital, nose, lip, chin, mandible, temple, ear, in front or behind the ear, genitalia, hand and foot <i>Medium risk:</i> Cheeks, forehead, scalp, and neck <i>Low risk:</i> Trunk, extremity (excluding hand/foot)
■ Size Lesions ≥6 mm on high-risk area Lesions ≥10 mm on medium-risk area Lesions ≥20 mm on low-risk area
■ Histologic subtype pattern Aggressive growth (morpheaform, fibrosing, sclerosing, infiltrating) Micronodular
■ Ill-defined clinical borders
■ Perineural invasion
■ Development in sites of prior radiation
■ Immunosuppression

Figure 107-7. Squamous cell carcinoma of the hand secondary to exposure to arsenic in welding flux.

Figure 107-8. Ulcerative squamous cell carcinoma.

Table 107-7 Squamous Cell Carcinoma: Higher-Risk Factors for Subclinical Invasion and Recurrence

■ Recurrent tumor
■ Anatomic location <i>High risk:</i> Central face, eyelid, eyebrow, periorbital, nose, lip, chin, mandible, temple, ear, in front or behind the ear, genitalia, hand, and foot <i>Medium risk:</i> Cheeks, forehead, scalp, and neck <i>Low risk:</i> Trunk, extremity (excluding hand/foot)
■ Size Lesions ≥6 mm on high-risk area Lesions ≥10 mm on medium-risk area Lesions ≥20 mm on low-risk area
■ Histology Poorly differentiated
■ Depth of invasion Clark level IV (lesion that involves the reticular dermis), V (lesion that invades into subcutaneous fat), or ≥4 mm
■ Perineural invasion
■ Rapid growth
■ Etiology Scar, chronic ulcer or inflammatory process, sinus tract, sites of prior radiation therapy
■ Immunosuppression

Accurate assessment of the higher-risk cutaneous SCCs is handicapped because of the lack of large prospective studies using multivariate analysis. Nine variables, however, have been identified as prognostic risk factors by retrospective analysis. Factors that may determine a higher risk for local recurrence, extensive subclinical invasion, and metastasis are noted in [Table 107-7](#).

Surgical Treatment of the Common Nonmelanoma Skin Cancers

A skin biopsy for diagnosis is important before treatment of any skin cancer. Fortunately, most NMSCs are small, low-risk lesions that respond with 90% to 95% cure rates to standard treatment techniques, including curettage and electrodesiccation, cryosurgery, radiation therapy, and surgical resection. Many skin cancers can be removed with elliptical excisions. Margins for low-risk SCC range from 0.5 to 1.0 cm. Margins for low-risk BCC range from 0.3 to 0.5 cm. Mohs surgery should be considered for BCCs

and SCCs that exhibit the higher-risk factors in [Tables 107-6](#) and [107-7](#). If Mohs surgery is not available, excision with careful frozen section control (with permanent section confirmation) is indicated. The fundamental oncologic principle of tumor clearance first and reconstruction second should be followed.

Mohs Surgery

Mohs surgery was developed by Frederick E. Mohs, a general surgeon from the University of Wisconsin, in the 1940s. Initially, a chemical fixative paste was applied to the skin to fix the tissue in situ; hence, the now outdated term *Mohs chemosurgery*. The fresh tissue technique, which omitted the chemical paste, was developed and refined in the 1970s. Mohs micrographic surgery is most useful for the treatment of higher-risk NMSC ([Tables 107-6](#) and [107-7](#)). Mohs surgery is usually performed under local anesthesia in an outpatient Mohs surgical unit. After removal of all gross tumor, the surgeon excises a thin layer of tissue with 2- to 3-mm margins. The tissue is mapped, color-coded for orientation, and sent to the technician for frozen section processing. The specimen is flexible and flattened, with the beveled peripheral skin edge placed in the same horizontal plane with the deep margin. In this plane, both the deep and peripheral margins are examined in one horizontal cut by frozen section analysis with total (theoretically 100%) margin control. Good-quality frozen sections may be achieved only by a skilled and experienced Mohs histotechnician. The Mohs surgeon functions as both a surgeon and pathologist. After histologic interpretation of the frozen section specimens, the precise anatomic location of any residual tumor can be identified and reexcised until all margins are tumor free ([Fig. 107-9](#)). The Mohs surgeon's ability microscopically to track subclinical tumor extensions results in the highest cure rate with maximal preservation of normal tissue. Soft tissue reconstruction can then be performed on the same day, after completion of Mohs surgical excision of the tumor ([Fig. 107-10](#)). A multidisciplinary approach involving Mohs, plastic, head and neck, and oculoplastic surgeons and radiation oncologists may be needed for extensive tumors. Mastering the Mohs technique is based on a steep learning curve that requires extensive training for optimal competence. Numerous Accreditation Council for Graduate Medical Education (ACGME) postgraduate fellowship training programs are available.

Figure 107-9. Mohs micrographic surgical technique.

Based on a review of all studies from all disciplines since 1950, the 5-year cure rate for treatment of previously untreated primary BCC by Mohs surgery is 99%, versus 90% to 93% for all non-Mohs modalities, including standard surgical excision.⁸³ For previously treated recurrent BCC, the 5-year cure

rates are 94% for Mohs versus 60% to 84% for non-Mohs modalities.⁸⁴ In general, Mohs surgery should be considered for NMSCs that are associated with a higher risk of recurrence after standard treatment and for tumors for which conservation of normal tissue is important. Risk factors for recurrence after standard treatment have been mentioned previously. Tumors for which maximal conservation of tissue may be important include tumors in the high-risk locations and tumors in young patients.

Figure 107-10. **A:** Patient with a 3- × 3-cm basal cell carcinoma on the right dorsal hand with mixed nodular and aggressive growth histologic pattern. **B:** Final Mohs surgery defect measuring 4.0 × 4.8 cm to the underlying tendon with preservation of tendon and nerve structures. Complete excision of the tumor required two Mohs stages (10 frozen sections). **C:** The defect was reconstructed immediately after achievement of clear margins under local anesthesia in the Mohs surgery unit using birhombic flap soft tissue reconstruction. **D:** Result 3 months after surgery.

Adjuvant and Primary Radiation Therapy

Radiation therapy may be useful for primary treatment of low-risk NMSCs. In experienced hands, primary radiation therapy may also be useful for higher-risk tumors with high cure rates. For cutaneous SCC with many high-risk factors and for those with extensive neurotropism, adjuvant prophylactic radiation therapy to the primary site and the primary draining lymph nodes may decrease the risks of local recurrence and regional nodal metastasis. Prophylactic adjuvant radiation therapy should also be considered for highly aggressive, deeply invasive BCCs that exhibit extensive neurotropism.

Locally Advanced and Metastatic BCC

The occurrence of locally advanced and metastatic BCC is uncommon. Uncontrolled Hedgehog (Hh) signaling is associated with the pathogenesis of both hereditary and sporadic BCC. Inactivating mutations on the tumor suppressor patched (PTCH) gene and activating mutations in the proto-oncogene smoothened (SMO) cause some BCC. These mutations result in the unregulated activation of the Hh pathway with an associated growth promotion and cancer development in tumor progenitor cells initially within the epidermis and hair follicle. Vismodegib represents the first hedgehog pathway

inhibitor approved by the FDA for the treatment of metastatic and locally advanced BCC, tumors deemed not candidates for surgery or radiation therapy. Initial objective response rates approach 30% for metastatic BCC and 43% for locally advanced BCC. Partial response rates are 30% for metastatic BCC and 22% for locally advanced disease. No complete responses were noted for metastatic BCC, and 20% complete responses for locally advanced BCC. Unfortunately, tumors may recur during or after discontinuation of the drug with a median duration of response about 8 months in both metastatic and locally advanced BCC patients. Adverse events occur in more than 30% of patients, 25% serious, and include most often muscle spasms, taste disturbances, alopecia, weight loss, and fatigue. Data are still immature with future study and long-term results needed for definitive conclusions.

Other Tumors of Interest

Hundreds of cutaneous tumors exist, and their description is beyond the scope of this chapter. Tumors that may be encountered by the surgeon for further management include Merkel cell carcinoma (MCC), sweat gland carcinoma, and dermatofibrosarcoma protuberans (DFSP).

8 MCC, or primary cutaneous neuroendocrine carcinoma, is an aggressive skin cancer with a higher overall mortality than melanoma (approximately 33% vs. 15%, respectively).¹¹¹ The incidence of MCC is low compared to other cutaneous malignancies (approximately 1,500 annually in the United States), but the number of cases has at least tripled over the last two decades.¹¹² While UV radiation and immunosuppression are considered important pathogenetic factors, recent findings suggest a virus (Merkel cell polyomavirus) as a contributing factor in the pathogenesis of MCC.¹¹³ MCC most commonly occurs in older, white individuals, with only 5% diagnosed before the age of 50 years. The majority of tumors (90%) are located on sun-exposed skin, equally distributed between the head and neck and extremities. The remaining 10% are located on the trunk and buttocks. Primary MCC typically presents as a new-onset, growing, red or purple, dome-shaped or subcutaneous nodule, frequently mistaken for a cyst, lipoma, or BCC (Fig. 107-11). The most common location of metastasis is the draining lymph node basin, followed by distant skin, lung, central nervous system, bone, and liver.¹¹⁴ MCC is a dermal small blue cell tumor with positive immunohistochemical staining for cytokeratin-20 (CK-20) in a characteristic paranuclear dotlike pattern. Small cell lung cancer, another neuroendocrine carcinoma histologically indistinguishable from MCC and occasionally CK-20 positive, expresses thyroid transcription factor-1, which is consistently absent in MCC.¹¹⁵ Newly established AJCC staging for MCC distinguishes stage I (primary tumor <2 cm without nodal disease), stage II (primary tumor ≥2 cm without nodal disease), stage III (microscopic or clinically apparent regional lymph node metastases), and stage IV disease (distant metastasis). Five-year survival rates for stages I, II, and III are 81%, 67%, and 52%, respectively. Stage IV disease carries a dismal 11% 2-year survival rate.⁹⁸ The majority (70%) of patients with MCC present with clinically localized disease (stage I or II), 25% have palpable lymphadenopathy (stage IIIB), and 5% present with distant metastases (stage IV).¹¹⁴ Multidisciplinary management of MCC is encouraged by the NCCN.^{116,117} Treatment consists of WLE with 1- to 2-cm margins. Postoperative radiation therapy to the primary tumor bed should be considered and is recommended for stage II disease.^{117,118} SLNB with immunostaining using CK-20 is highly recommended for all primary MCC to stage the nodal basin and guide regional nodal therapy.^{116,118–120} Regional lymph node metastases can be treated by regional therapeutic lymphadenectomy and/or radiation therapy. Adjuvant radiation therapy to the regional nodal basin should be considered if SLNB is not performed or is thought to be false negative. For nonsurgical candidates, primary treatment of MCC with radiation therapy may also be considered.¹²¹ Chemotherapy has failed to demonstrate a survival benefit in an adjuvant setting in the treatment of localized or regional MCC and should be reserved for distant metastatic (stage IV) disease.¹²²

Figure 107-11. Merkel cell carcinoma.

Sweat gland carcinomas represent a broad scope of neoplasms with variable risk for local, regional, or distant metastasis, most commonly of eccrine or apocrine origin.¹²³ These are rare tumors (0.005% of skin malignancies) that have multiple histologic subtypes, giving rise to a diverse and confusing nomenclature. The aggressive types of sweat gland carcinomas have a propensity for both local recurrence and regional or systemic metastasis. Clinically, these tumors appear as indurated plaques, papules, or nodules commonly on the head and neck or extremities and are red, blue, pink, or skin colored. Histologic subtypes that are associated with a risk of regional lymph node or systemic metastasis include aggressive digital papillary adenocarcinoma, hidradenocarcinoma, and eccrine carcinoma. Recommended treatments have included wide excision of the primary tumor with consideration of SLNB for high-risk lesions commonly based on size, mitotic rate, histologic grade of atypia, or immunosuppression.¹²³ Postoperative radiation therapy may also be considered as adjuvant treatment.

9 DFSP is a rare soft tissue sarcoma (1% of all soft tissue sarcomas) with a propensity for local recurrence rather than systemic metastasis. It is a spindle cell tumor that characteristically demonstrates immunoreactivity to CD34. Adults in their third to fifth decades are most commonly affected, but DFSP may occur in children or the elderly. These tumors appear as firm flesh-colored to dull red plaques that may be mistaken for keloids or hypertrophic scars. Although DFSPs may appear discrete, they characteristically demonstrate extensive subclinical involvement, which makes this sarcoma difficult to manage. Histologically, these sarcomas are identified by their fingerlike projections of spindle cells that likely account for the increased risk of tumor recurrence. Standard histologic processing makes it difficult to track these fingerlike projections. Treatment commonly consists of WLE with more comprehensive margin assessment or Mohs surgery, depending on patient and tumor factors. A multidisciplinary approach utilizing the expertise from several fields (surgical subspecialties, pathology, Mohs surgery) may be needed to achieve the goals of complete tumor extirpation, low local recurrence rates, and reconstructive repair.^{124,125} Reconstruction involving extensive undermining should be avoided and tissue rearrangement should be delayed until negative histologic margins are confirmed to prevent possible tumor seeding from persistent disease. Radiation therapy is indicated when negative margins cannot be obtained.¹²³ Imatinib mesylate has shown promising results in the treatment of unresectable or metastatic DFSP.^{126,127}

Chapter 108

Sarcomas of Soft Tissue and Bone

Sandra L. Wong

Key Points

- 1 Sarcomas are a rare and heterogeneous group of cancers that arise from mesoderm-derived elements such as muscle, fat, nerve/nerve sheath, cartilage, blood vessels, bone, and other connective tissue. They are histologically distinct from cancers of epithelial origin.
 - 2 Clinical behavior and prognosis are largely defined by anatomic location, tumor grade, size, and ability to achieve complete surgical resection.
 - 3 For extremity sarcomas, radiotherapy is indicated for high-risk tumors to decrease disease relapse and improve survival. Limb-sparing procedures are favored in order to maximize functional outcomes.
 - 4 Surgical resection is the cornerstone of treatment for intra-abdominal or retroperitoneal sarcomas. Complete resection may require en bloc resection of adjacent or involved organs, most commonly of the kidney and colon.
 - 5 The use of imatinib, a selective tyrosine kinase inhibitor, in the management of gastrointestinal stromal tumors (GISTs), is a paradigm for the successful use of targeted molecular therapies.
 - 6 Increasing use of multimodality therapies including surgical resection, chemotherapy, and radiotherapy has dramatically improved outcomes for sarcomas such as osteosarcoma and Ewing sarcoma.
-

1 Sarcomas are a heterogeneous group of cancers that arise from mesenchymal cells, or mesoderm-derived elements, including muscle, fat, nerve/nerve sheath, cartilage, blood vessels, bone, and other connective tissue. Sarcomas of soft tissue and bone are considered two distinct categories. Though mesoderm-derived elements comprise nearly two-thirds of the body's mass, sarcomas are relatively rare. In 2016, just over an estimated 15,000 new cases of soft tissue and bone sarcoma were expected to be diagnosed in the United States,¹ which account for less than 1% of all new cancers. Sarcomas also represent an extremely heterogeneous group of cancers, but taken together, 5-year overall survival is about 50% to 60%.^{2,3} Anatomic location, tumor size, grade, and histopathology, are important determinants of clinical presentation, treatment, and prognosis.

The Greek word “sarkoma,” meaning “fleshy excrescence” is the origin for the term “sarcoma.” As early as AD 130 to 200, these fleshy tumors were regarded as cancerous by Galen.⁴ With the evolution of light microscopy and cellular pathology, there was increasing recognition of soft tissue sarcomas. Sarcomas, then called “soft cancers,” were differentiated from carcinomas by neuroanatomist Charles Bell as early as 1816. Vichow refined the definition of sarcoma as “new formations of connective tissue,” and developed classifications according to microscopic features which separated sarcomas from carcinomas of epithelial origin. Modern foundations for the description and histogenic descriptions of sarcoma are attributed to the work of James Ewing, who over the course of his pathology career refined the classification of sarcomas, including the importance of grade in disease outcome.⁵

Multimodality therapies, including surgery, radiation, and chemotherapy, have been combined to improve local and systemic tumor control. Over the past few decades, an evolution of multidisciplinary approach has enabled successful treatment options to evolve from radical amputation to limb-sparing procedures for extremity sarcoma. As refinements in pathologic classification continue, so does progress in the use of treatment modalities. Modern molecular diagnostics are increasingly being translated to clinical practice, and tailored treatment options are being developed as the histologic diversity of soft tissue sarcomas is continually elucidated and better understood. As with many rare tumors, referral to high-volume centers with clinical expertise is indicated when feasible.

EPIDEMIOLOGY

Soft tissue sarcoma can occur in all age groups and are equally distributed between genders. While the median age at diagnosis varies by histopathologic subtype, sarcomas are relatively rare in the adult population. However, sarcomas are among the most common cancers seen in children and young adults, representing approximately 15% of pediatric malignancies and often occurring in children under 5 years of age.⁶ There are nearly 75 distinct histopathologic subtypes. Further, sarcomas can occur at any anatomic site, though most arise in the extremities and trunk, and accordingly, anatomic site influences treatment and outcomes (Fig. 108-1).

While the vast majority of sarcomas arise spontaneously, there are some predisposing conditions to consider. Sarcomas are not thought to be the result of malignant degeneration of a long-standing benign lesion such as a lipoma. An injury or other traumatic incident may lead to the initial recognition of a mass, but there are no data to support the notion that antecedent trauma leads to the development of either soft tissue or bony sarcomas. Clinical evaluation and subsequent workup, including biopsy if indicated, should be able to distinguish malignant growths from a variety of benign posttraumatic lesions, such as myositis ossificans, which must be differentiated from an extrasosseous osteogenic sarcoma.

Toxic exposures have been related to the development of sarcoma. Largely of historic interest, the industrial use of thorium dioxide (Thorotrast), arsenic, and vinyl chloride led to accumulation of toxins in the liver and were associated with the development of hepatic angiosarcomas. Several other predisposing conditions are known to be associated with the development of sarcoma. The classic Stewart–Treves syndrome was originally described in patients with lymphedema following radical mastectomy and radiation for breast cancer who then developed lymphangiosarcoma of the affected arm.⁷ Since then, long-standing extremity edema from other causes has also been linked to the development of lymphangiosarcomas. Kaposi sarcoma was previously an uncommon cutaneous vascular tumor thought limited to elderly men of Mediterranean origin. In the early 1980s it became one of the first described opportunistic disease associated with HIV infection. Though the incidence of HIV-associated Kaposi sarcoma has markedly declined with effective antiretroviral therapy, it remains an important cause of morbidity among HIV-infected patients and other immunosuppressed patients such as renal allograft recipients.⁸⁻¹⁰

Figure 108-1. Distribution of sarcoma by anatomic location. (Adapted from Brennan MF, Antonescu CR, Moraco N, et al. Lessons learned from the study of 10,000 patients with soft tissue sarcoma. *Ann Surg* 2014;260:416–422.)

Various types of radiation have been implicated in the delayed development of sarcomas. For example, incidental ingestion of luminous paint containing ²²⁶radium by factory workers led to the development of osteosarcomas. With the increasing use of external beam radiation in cancer treatment, there has been a noted increase in the modern incidence of secondary sarcoma in patients previously treated with radiation for a variety of malignancies. Following median latent periods of approximately 8 years (range 6 to 20 years), radiation-associated sarcomas are being increasingly diagnosed in previously radiated areas. Common radiation-associated sarcoma subtypes are angiosarcomas, undifferentiated pleomorphic sarcoma, fibrosarcoma, and leiomyosarcoma, and they are commonly, but

not uniformly, high grade.^{11,12} Notably, with the advent of breast conservation therapy for breast cancer (consisting of partial mastectomy/lumpectomy and adjuvant radiation therapy), there should be an appropriate index of suspicion for breast angiosarcomas with findings of skin changes on the breast (Fig. 108-2).

GENETIC CANCER SYNDROMES

While the vast majority of sarcomas are sporadic, numerous genetic alterations are associated with both bone and soft tissue sarcomas.¹³ There are well-described genetic predispositions to sarcoma. Patients with neurofibromatosis type 1 (NF-1, or von Recklinghausen disease) have mutations in the neurofibromin 1 or 2 gene (*NF1* or *NF2*, respectively) which are associated with the development of malignant peripheral nerve sheath tumors (MPNSTs) in an estimated 5% of patients over a lifetime.¹⁴ A genetic predisposition to desmoid tumors or desmoid fibromatosis is associated with familial adenomatous polyposis (FAP), or Gardner syndrome which is the result of germline mutations in the adenomatous polyposis coli (*APC*) gene.^{15,16} Intra-abdominal and extremity desmoids are a common extracolonic manifestation of FAP and can be a source of increased morbidity in these patients following proctocolectomy for the prevention or treatment of colon cancer.¹⁷

While somatic activation of c-KIT and overexpression of KIT protein are well described in the pathogenesis of gastrointestinal stromal tumors (GISTs), there are described germline mutations as well. Familial GIST syndrome has been ascribed to germline mutation in c-KIT as well as in the *SDHB*, *SDHC*, and *SDHD* succinate dehydrogenase subunits, in association with Carney triad (GIST, pulmonary chondromas, extra-adrenal paragangliomas) or Carney–Stratakis syndrome (GIST, paraganglioma).^{18,19}

One well-documented mechanism of sarcoma development is the inactivation of tumor suppressor genes. Retinoblastoma was known to be associated with a mutation in the retinoblastoma gene (*RB1*), a 13q chromosomal deletion. Investigation of the link between familial retinoblastoma and osteosarcoma led to the discovery that a genetic defect in *RB1* also plays a role in the pathogenesis of sarcomas.^{20,21}

Another inherited defect of a tumor suppressor gene associated with soft tissue sarcomas is the Li–Fraumeni syndrome, caused by an inherited mutation in the *p53* gene, a key growth-regulatory gene.²² Germline mutations in affected patients are associated with high incidences of childhood rhabdomyosarcomas, breast cancer, brain tumors, lung cancer, and leukemias).²³ *p53* abnormalities may be seen in as many as 60% of osteosarcomas and malignant fibrous histiocytomas, as well as approximately 33% of other sarcomas.²⁴ Several oncogenes that can induce malignant transformation and drive proliferation have also been associated with sarcoma development, including amplifications of *N-myc*, *c-erbB2*, and members of the *ras* family.²⁵

Figure 108-2. Radiation-associated angiosarcoma. This 79-year-old woman developed skin changes on her breast 7 years after breast conservation therapy (lumpectomy and radiation therapy) for a 2-cm invasive ductal adenocarcinoma. Salvage mastectomy was performed.

Cytogenetic aberrations have been recognized in a number of soft tissue sarcomas.¹³ Several histologic subtypes of sarcomas have each been found to have specific genetic alterations – usually simple karyotypes including fusion genes due to reciprocal translocations or specific point mutations (Table 108-1). These chromosomal translocations serve as powerful diagnostic markers and may be important in determining tumor biology and subsequent tumor behavior. For example, identification of

the translocation of t(X;18)(p11;q11) can confirm the diagnosis of synovial sarcoma if there is any doubt of its histopathology. There are data to suggest that the SYT-SSX1 fusion transcript carries a worse prognosis than the SYT-SSX2 fusion transcript, with median survivals of 6.1 years and 13.7 years, respectively.^{26,27}

A better understanding of the molecular biology of sarcomas has revolutionized diagnosis of specific histopathologic subtypes and has elucidated potential pathways for targeted molecular therapy.

SOFT TISSUE SARCOMAS

Clinical Presentation

The most common presentation of a soft tissue sarcoma is that of an asymptomatic mass. Sarcomas tend to grow in a centrifugal fashion, usually pushing surrounding structures away rather than directly invading them. Encasement of structures can occur, but again, this largely occurs in the absence of direct invasion. Compression generally does not produce pain, swelling, or obstructive symptoms until the tumors become quite large. Because of surrounding anatomic structures, some tumors of the extremities tend to be detected at a relatively smaller size, whereas tumors of the retroperitoneum are infrequently smaller than 10 cm at the time of presentation.⁵ Even very large abdominal or retroperitoneal sarcomas present with nonspecific abdominal symptoms such as fullness, early satiety, or minor abdominal discomfort (Fig. 108-3). The differential diagnosis for a soft tissue sarcoma includes many types of benign lesions (e.g., lipomas, leiomyomas, and neuromas) but also other malignant lesions (e.g., primary carcinoma, lymphoma, metastatic disease from melanoma, or testes cancer).

In general, the vast majority of soft tissue masses tend to be benign, but concerning features which should prompt a higher index of suspicion for malignancy include large size (>5 cm), deep location (subfascial, intramuscular, or intra-abdominal), variations in texture on examination, immobile nature or noted fixation to underlying structures, or changes to an existing lesion (increasing size or worsening compressive symptoms). No tumor markers for sarcomas exist, so serum bloodwork is generally not useful in the evaluation of soft tissue masses.

Diagnosis

Diagnostic Imaging

Accurate radiologic imaging is critical in the diagnostic workup of sarcoma to provide information about the precise location and extent of the primary tumor. Computed tomography (CT) scans and magnetic resonance imaging (MRI) are the most important studies for evaluating the resectability of soft tissue sarcomas, providing definition of the primary tumor in relation to bone, muscle, neurovascular structures, and adjacent organs. Plain radiographs of bones and radionuclide bone scans rarely provide useful information regarding invasion of bone by the tumor. Both CT and MRI can provide critical information for treatment planning. While MRI may be preferred for extremity sarcomas, CT is often the modality of choice for abdominal and retroperitoneal tumors. However, there appears to be no difference between high-quality CT and MRI in terms of ability to determine involvement of nearby structures, bone, or neurovascular structures.²⁸⁻³⁰

Table 108-1 Cytogenetic Abnormalities in Soft Tissue Sarcoma Subtypes

Histologic Subtype	Chromosomal Translocation	Fusion Gene
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14) t(1;13)(p36;q14)	PAX3-FKHR PAX7-FKHR
Alveolar soft part sarcoma	t(X;17)(p11;q25)	ASPL-TFE3
Clear cell sarcoma	t(12;22)(q13;q12)	EWS-ATF1
Desmoplastic small round cell tumor	t(11;22)(p13;q12)	EWS-WT1
Dermatofibrosarcoma protuberans	t(17;22)(q21;q13)	COL1A1-PDGFB
Endometrial stromal sarcoma	t(7;17)(p15;q21)	JAZF1-JJAZ1
Ewing sarcoma/PNET	t(11;22)(q24;q12) t(11;22)(q22;q12)	EWS-FLI1 EWS-ERG
Extraskeletal myxoid chondrosarcoma	t(9;22)(p13;q12) t(9;17)(q22;q11) t(9;15)(q22;q11)	EWS-CHN TAF2N-NR4A3 TCF12-NR4A3
Fibrosarcoma	t(12;15)(p13;q26)	ETV6-NTRK3
Inflammatory myofibroblastic tumor	t(1;2)(q22;p23) t(2;19)(p23;p13) t(2;17)(p23;q23) t(2;2)(p23;q13)	TPM3-ALK TPM4-ALK CLTC-ALK RANB2-ALK
Fibromyxoid sarcoma	t(7;16)(q33;p11) t(11;16)(p11;p11)	FUS-CREB3L2 FUS-CREB3L1
Myxoid and round cell liposarcoma	t(12;16)(q13;p11) t(12;16)(q13;p12)	TLS-CHOP
Synovial sarcoma	t(X;18)(p11;q11)	SYT-SSX1 SYT-SSX2

Figure 108-3. Dedifferentiated liposarcoma of the retroperitoneum. This 51-year-old woman presented with only vague symptoms of abdominal fullness from a very large retroperitoneal mass. The CT scan demonstrates a heterogeneous soft tissue mass in the upper abdomen (A), which blends into a more fatty component (B) which encases the left kidney and displaces abdominal contents. She underwent radical resection en bloc left nephrectomy, distal pancreatectomy, splenectomy, left colectomy, and segmental resection of inferior vena cava.

Imaging is also important as part of the extent of disease workup. Because sarcomas are known to predominantly metastasize to the lungs, directed chest imaging should be performed at time of diagnosis. Chest radiography (CXR) may be used, but CT scans are increasingly being used as the primary screening examination of choice for higher-risk patients, such as those with high-grade lesions or tumors larger than 5 cm.³¹ Any abnormal CXR must be followed by a chest CT scan using appropriate nodule protocol, usually involving thinner sections and often not requiring the use of IV contrast, for more detailed evaluation of potential pulmonary metastases (Fig. 108-4). CT of the chest, abdomen, and pelvis should be considered in any patient with a myxoid liposarcoma of an extremity because this subtype often metastasizes to the abdomen or other “fat pads” such as the axilla.³²

MRI is the most commonly used imaging modality for extremity sarcomas.^{28,33} Sequencing routinely

involves axial T2-weighted and precontrast/postcontrast T1-weighted images. Contrast enhancement with gadolinium is crucial for detecting and characterizing lesions with coronal, sagittal, and other reconstructions. This imaging modality can accurately delineate between muscle groups and distinguish among tumor and neurovascular structures (Fig. 108-5). Magnetic resonance angiography (MRA) can be performed if more accurate delineation of vascular structures is required for surgical planning.

Positron emission tomography (PET) scanning using fluoro-13-deoxyglucose also offers the potential for noninvasive analysis of tumor metabolism and has been shown to correlate with both tumor grade and response to treatment for many types of cancers.^{34–37} PET maybe helpful in distinguishing between benign and malignant lesions and may be useful for assessing response to treatment.³⁸ However, its accuracy and potential for false-negative results are still incompletely defined, so its use is not routine, either for staging or for surveillance. Even with a PET scan, formal imaging with contrasted CT or MRI is necessary so costs and extent of imaging should be considered.

Figure 108-4. Pulmonary metastasis. A noncontrasted CT scan of the thorax demonstrates a 1.1-cm noncalcified nodule consistent with pulmonary metastasis in the upper lobe of the right lung.

Figure 108-5. Extremity sarcoma. MRI demonstrates a 20-cm low-grade myxoid liposarcoma. **A:** Coronal reconstruction demonstrates location in the distal right thigh. **B:** Axial images show displacement of the popliteal vessels and vastus medialis anteriorly; the common tibioperoneal nerve and biceps femoris laterally; and, the semimembranosus and semitendinosus muscles medially.

Diagnostic Biopsy

Properly performed biopsies are critical in directing a multimodality treatment approach. Image-guided techniques are increasingly being applied so that open biopsy is not mandatory. Fine-needle aspiration (FNA) is frequently used for the evaluation of enlarged lymph nodes, thyroid nodules, or breast masses. However, FNA often does not provide sufficient materials for definitive histopathologic diagnosis, especially for an index presentation. In select cases, FNA may be useful to demonstrate recurrent disease. Core-needle biopsy (CNB) is considered the initial procedure of choice for diagnosis of soft tissue sarcomas.³⁹ CNB retrieves sufficient material for immunohistochemical staining, and when necessary, for cytogenetic analysis or flow cytometry. Image-guided CNB, either using CT or ultrasound, allows for the biopsy of deep masses that may not be easily palpable and can help target suspicious areas in a heterogeneous field for better diagnostic value. An adequate sample from a viable area of sarcoma is required for definitive diagnosis and accurate grading. CNB is associated with low complication rates (<1%), with major concerns related to bleeding.⁴⁰ Concerns about recurrence along the tract are obviated with the use of a sheathed needle device and/or excision of the biopsy tract at the time of definitive resection when possible.

Open surgical biopsy, or incisional biopsy, is uncommonly needed with increasing success of CNB.⁴¹ However, open biopsy should be considered when core-needle specimens yield nondiagnostic findings and if preoperative diagnosis is definitely required for treatment planning. Several important technical factors must be considered when performing an incisional biopsy. Incisions must be oriented along the long axis of extremities to facilitate complete resection with definitive surgical management. Transverse incisions in the extremity often commits the patient to more extensive procedures than would be otherwise necessary, potentially compromising the ability to obtain clear margins with definitive limb-sparing procedures. Attempts to enucleate the sarcoma within its pseudocapsule is discouraged, though excisional biopsy can be considered as the primary approach for small, superficial lesions.⁵ Extensive dissection during a biopsy, including undermining surrounding subcutaneous layers, should be consciously avoided in order to contain the extent of disease and best manage subsequent procedures. Attention to meticulous hemostasis also prevents extensive “seeding” of the area.

PATHOLOGIC CLASSIFICATION

Histopathologic designation of soft tissue sarcomas reflects an extremely heterogeneous group of tumors. Sarcomas are generally classified according to the tissues they mimic rather than the type of tissue from which the tumor arises. Some sarcomas have no recognizable normal tissue counterpart and are characterized by other distinguishing histologic features.^{5,42} The various types of benign and malignant soft tissue tumors are noted in [Table 108-2](#). The development of specialized markers for identifying individual types of sarcoma has led to greater precision in their classification. Helpful immunohistochemical stains include the intermediate filaments (i.e., vimentin, keratin) and muscle markers (i.e., desmin, actin). More specific markers can be instrumental in diagnosis, such as myoglobin staining for rhabdomyosarcomas. In a small proportion of tumors (approximately 10% in most series), the tumor cells are so poorly differentiated that no specific histogenesis can be determined, and these may be designated as spindle cell sarcomas or undifferentiated pleomorphic sarcomas.

One of the most critical pieces of pathologic information for clinicians treating sarcoma patients is histologic grade. Histologic grade is assessed based on the expert assessment of degree of cellular atypia, the frequency of mitotic figures, and the presence or absence of spontaneous tumor necrosis. While grading criteria have undergone numerous revisions over the years, in general, low-grade tumors have relatively little cellular atypia, few mitoses, and no tumor necrosis. High-grade tumors show a significant degree of necrosis in addition to atypia and frequent mitotic figures ([Fig. 108-6](#)). A consistently applied grading system discriminates between tumors with good prognosis (low grade) and those with relatively poorer prognosis (high grade). In the past, various grading systems have been used (2-tiered systems (low vs. high); 3-tiered systems; and 5-tiered systems). The current American Joint Commission on Cancer (AJCC) staging system recognizes a classification system ranging from grade 1 (G1, well differentiated) to grade 3 (G3, undifferentiated) tumors.^{43–45} Evaluation typically takes histology, tumor differentiation, mitotic count, and tumor necrosis into account. There can be disagreement about grading schemas and expert pathology opinion can vary from center to center.^{46,47} As such, it is important to take note of tumor classification when interpreting results from clinical trials or retrospective reports.⁴⁸ The metastatic potential for low-grade lesions is approximately 5% to 10% compared to up to 50% to 60% for high-grade tumors.² For lesions in which disparate areas exist, the highest grade encountered is generally used to categorize the tumor.

Table 108-2 Histologic Classification of Soft Tissue Tumors

Connective Tissue	Benign Soft Tissue Tumor	Malignant Soft Tissue Tumor (Sarcoma)
Adipocyte	Lipoma	Liposarcoma
Fibrous tissue (Fibroblastic)	Fibroma	Fibrosarcoma, Fibromyxoid sarcoma
Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma
Smooth muscle	Leiomyoma	Leiomyosarcoma
Bone	Osteoma	Osteosarcoma
Cartilage	Chondroma	Chondrosarcoma
Synovium	Synovioma	Synovial sarcoma
Blood vessels	Hemangioma Hemangiopericytoma	Angiosarcoma Epithelioid hemangioendothelioma
Lymphatics	Lymphangioma	Lymphangiosarcoma
Nerve	Neurofibroma	Malignant peripheral nerve sheath tumor, Neurofibrosarcoma
Mesothelium	Benign mesothelioma	Malignant mesothelioma
Histiocytes	Benign fibrous histiocytoma	Undifferentiated pleomorphic sarcoma/ malignant fibrous histiocytoma
Uncertain/other		Ewing sarcoma/primitive neuroecto- dermal tumor Alveolar soft-part sarcoma Epithelioid sarcoma Clear cell sarcoma of soft tissue Desmoplastic small round cell tumor

STAGING

Because of the prognostic importance of staging, stage classification of the primary tumor is based on both clinical and histologic information. The usual TNM classification used by the AJCC⁴⁵ for other solid tumors is modified to a GTNM system (Table 108-3) for soft tissue sarcomas.

Figure 108-6. Histologic grading of sarcomas. Photomicrographs demonstrate the appearance of different grades within the same histologic subtype. **A:** Well-differentiated liposarcoma (lipoma-like) of the retroperitoneum with noted few atypical lipoblasts. **B:** High-grade, dedifferentiated liposarcoma of the retroperitoneum with highly atypical lipoblasts. Table 108-3 American Joint Commission on Cancer (AJCC): GTNM Classification and Stage Grouping of Soft Tissue Sarcomas

Classification	Description
Tumor Grade	
GX	Grade cannot be assessed
G1	Grade 1
G2	Grade 2
G3	Grade 3
Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of a primary tumor
T1	Tumor <5 cm in greatest diameter
T1a	Superficial tumor
T1b	Deep tumor
T2	Tumor <5 cm in greatest diameter
T2a	Superficial tumor
T2b	Deep tumor
Lymph Node Involvement	
NX	Regional lymph nodes cannot be assessed
N0	No known metastases to lymph nodes
N1	Regional lymph node metastases
Distant Metastasis	
MX	Presence of distant metastasis cannot be assessed
M0	No known distant metastasis
M1	Known distant metastasis
Stage Grouping	
Stage I	G1-2, T1a, N0, M0 G1-2, T1b, N0, M0 G1-2, T2a, N0, M0 G1-2, T2b, N0, M0
Stage II	G3-4, T1a, N0, M0 G3-4, T1b, N0, M0 G3-4, T2a, N0, M0
Stage III	G3-4, T2b, N0, M0
Stage IV	Any G, Any T, N1, M0 Any G, Any T, N0, M1

Not including Gastrointestinal stromal tumors.

In soft tissue sarcoma, the primary tumor is categorized according to size (<5 cm = T1, >5 cm = T2) and depth relative to the fascia (entirely above the fascia, or “superficial” = a; invading or entirely below the fascia, or “deep” = b). Because depth of tumor seemed to add significant prognostic information, this distinction was added to the 1998 edition of the AJCC staging system. One series of 215 patients with superficial extremity sarcomas documented a 10-year survival rate of 85% despite that 53% of tumors were high grade and 25% of tumors were 5 cm or larger.⁴⁹ Though the cutpoint between small and large tumors is 5 cm, tumors larger than 10 cm seem to have an even worse prognosis.⁵⁰ When 316 patients with soft tissue sarcoma were grouped into four subgroups (<5 cm, 5 to 10 cm, 10 to 15 cm, and >15 cm), each subgroup had a distinct prognosis (84%, 70%, 50%, and 33%, respectively).⁵¹

2 For nonmetastatic sarcomas, location is a major determinant of survival (Fig. 108-7). Nodal metastasis of soft tissue sarcomas is rare (far less than 5% of cases), with the exception of a few histologic subtypes for which the incidence of nodal involvement may be between 10% and 20%. These subtypes include angiosarcoma, embryonal rhabdomyosarcoma, epithelioid sarcoma, synovial sarcoma, and clear cell sarcoma.⁵² In the past, node involvement in sarcoma received classification as stage IV disease because of the associated poor prognosis. However, evidence suggested that lymph node metastases were associated with significantly better outcomes than systemic disease in the seventh edition of the AJCC staging system, and that survival was equivalent to stage III disease after directed lymphadenectomy.^{53,54} Therefore, node involvement (N1) was reclassified as stage III disease in the absence of distant metastasis (M0).

Figure 108-7. Soft tissue sarcoma disease-specific survival by site. Hash marks indicate censored patients. (IA = intra-abdominal; Retro = retroperitoneal). (From Brennan MF, Antonescu CR, Moraco N, et al. Lessons learned from the study of 10,000 patients with soft tissue sarcoma. *Ann Surg* 2014;260:416–422.)

By far the most common site of metastasis is the lungs though metastases to other sites do occur. Metastases to the liver should be considered with GIST or leiomyosarcoma.

TREATMENT

Principles of Surgical Resection

Complete surgical resection remains the cornerstone of treatment for soft tissue sarcomas. Performing a wide excision of the tumor with negative margins is the goal of resection with curative intent. Simple enucleation, if even possible, usually results in inadequate resection and should be avoided. Technical aspects of resection must take into consideration the anatomic location and extent of disease. Often, soft tissue sarcomas are surrounded by a zone of compressed reactive tissue that forms a pseudocapsule. Care should be taken to avoid entry into the tumor and pseudocapsule during course of dissection. Enucleation commonly results in microscopically positive margins and resection can be considered though anatomic location may preclude effective clearance of margins even with a second operation.

Metallic clips placed in the tumor bed following resection can help define the limits of resection and aid in surveillance as well as the planning of future treatment. Suction drainage catheters are routinely used to obviate postoperative seroma formation following resection of extremity or truncal sarcomas. Drains should be placed close to the incision so that the site can be included in a postoperative radiation field and to minimize the extent of proximal involvement if amputation ever becomes necessary. A unique characteristic of sarcoma is the lack of metastasis to regional lymph nodes. If regional lymphadenopathy is discovered in conjunction with a diagnosis of sarcoma, therapeutic lymphadenectomy can be considered since clearance of disease may be associated with improved outcomes.^{52,53} For selected histopathologic subtypes, in patients with clinically negative node examination, there may be a role for sentinel lymph node biopsy to identify occult micrometastatic disease.⁵⁵

Taken together, sarcomas of the upper and lower extremities and trunk make up the majority of soft tissue sarcomas. Large truncal tumors may require reconstruction with a myocutaneous flap or prosthetic materials if resultant defects cannot be closed primarily (Fig. 108-8). Largely of historic interest now, radical amputations were once the mainstay of treatment for extremity sarcoma, but modern surgical approaches involve limb-sparing procedures (Fig. 108-9), which maximize functional outcomes. As recently as the 1970s, more than 50% of all soft tissue sarcomas of the extremity were treated with radical amputations. The accepted standard of care changed after the group at the National Cancer Institute, led by Rosenberg,⁵⁶ published the results of a randomized trial of limb-sparing resection plus adjuvant radiation therapy compared to amputation, finding no differences in disease-free survival rates (71% vs. 78%, respectively) and the overall survival rates (83% vs. 88%, respectively) at 5 years. This trial demonstrated that amputation was not mandatory and in 1985, a National Institutes of Health consensus statement recommended limb-sparing procedures for most patients with high-grade extremity sarcomas.⁵⁷ Radical amputations, such as hemipelvectomy, hip disarticulation, or forequarter amputation, are now reserved for patients who are not suitable candidates for limb-sparing approaches, usually because of extent of disease, bony or joint invasion, or for otherwise unsalvageable recurrence after previous limb-sparing surgery (Fig. 108-10). There is no improvement in survival with this

approach under these circumstances and serious morbidity must be taken into account.⁵⁸

Acceptance of multimodality therapy has led to the ability to perform wide excisions while preserving function when treating extremity or truncal soft tissue sarcomas.^{5,59,60} Radiation can be employed in the neoadjuvant or adjuvant setting, and evidence from randomized trials as well as retrospective studies support similar local control and progression-free survival rates with both strategies. A phase III trial in which patients were randomized to preoperative or postoperative radiation showed similar primary outcomes, but found that preoperative radiation was associated with much higher wound complications (35% vs. 17%, respectively) and this was especially true for lower extremity tumors. The interesting tradeoff was a higher rate of late treatment effects in the postoperative radiation group, attributed to relatively higher treatment doses and volumes.^{61,62}

Judicious use of radiation has allowed for the sparing of major neurovascular structures, though if necessary, arteries and/or veins can be resected en bloc with the tumor and subsequent reconstruction can be done with autologous or prosthetic graft materials. In cases of neurologic compromise, customized adjuncts from experienced physical medicine departments can help restore reasonable function. For instance, resultant foot drop from peroneal neuropathy can be managed with an ankle-foot orthotic and gait training. In some cases, resection should be planned in conjunction with a plastic surgeon to provide complex soft tissue reconstruction with microvascular free flaps if the size of defect following resection prohibits primary closure.

Adjuvant and Neoadjuvant Therapies

3 The role of external beam radiotherapy is best defined by a trial comparing limb-sparing surgery alone with limb-sparing surgery with adjuvant radiation, showing improved 10-year local recurrence rates with radiation. In high-grade sarcomas, the recurrence rate was 0% versus 22%, respectively, though no significant effect on overall survival was appreciated.⁶³ Certainly, in the setting of involved surgical margins which could not otherwise be resected, adjuvant radiation therapy is associated with improved local control.^{3,64}

There is controversy regarding the optimal use of radiation in the preoperative setting compared to the postoperative setting for extremity and truncal sarcomas. Radiation in the adjuvant setting with either external beam radiation or brachytherapy has long been the standard approach.³ Typically, the entire surgical bed and drain sites are included in the field, along with wide margins around the sarcoma. Hemoclips marking the site of resection can be placed at the time of resection to help with radiation planning. It is important that an individual approach be taken with each patient since radiation can result in severe complications when used inappropriately ([Table 108-4](#)). For example, the entire circumference of the extremity should not be irradiated because massive lymphedema may result. Severe fibrosis, necrosis, fractures, and contractures can also occur with focused treatment and result in impaired function. Wound healing may be compromised in patients undergoing adjuvant radiation and in selected cases, use of rotational flaps for coverage can prevent or minimize chronic wound healing problems.⁶⁵ Similarly, radiation must be used judiciously in sensitive areas since nearby visceral structures are exquisitely sensitive to higher doses of radiation. Dose-limiting toxicity must be considered when recommending such therapies.

Figure 108-8. Chest wall sarcoma. A 20-year old man with a 7.5-cm right posterior chest wall epithelioid sarcoma involves the 11th and 12th ribs as seen on CT scan (A) and on physical examination (B). Chest wall resection was performed, including a portion of diaphragm. Resulting chest wall defect (C) was repaired using prosthetic mesh (D).

An alternate approach to adjuvant radiation is brachytherapy, which involves the placement of multiple catheters or seeds in the tumor resection bed to administer iridium.¹⁹² Unlike the several week course needed to complete external beam radiation, a course of brachytherapy can be completed in a few days' time. In theory, brachytherapy produces less radiation scatter in critical areas, decreasing toxicity while obtaining equivalent functional outcome.⁶⁶ However, brachytherapy requires special equipment and can involve technically complex treatment planning by an experienced radiation oncologist. From a therapeutic standpoint, brachytherapy and external beam radiation appear to be equivalent when properly administered. There is increasing interest in the use of intraoperative radiation therapy (IORT), though its effectiveness is unproven. If IORT is employed, it is currently done in conjunction with a planned external beam boost dose.⁶⁷

Patients with high-risk (large [>10 cm], high-grade) extremity sarcomas should be considered for preoperative treatment with chemotherapy or with chemoradiation since overall local control rates are disappointing with postoperative radiation alone.⁵⁹ Local control rates were considerably higher when large tumors were treated before surgery and in some cases, tumors initially considered unresectable without amputation shrank sufficiently to permit limb-sparing resection. There are several benefits of preoperative radiation. With the tumor in situ, there tends to be a smaller overall treatment volume and the theoretical advantages of more effective radiation because it is being delivered to an undisturbed tumor bed. There is also the potential benefit of decreased seeding during the course of resection and improved margin status because the radiation may shrink the tumor's pseudocapsule and render it relatively acellular. However, there is one major disadvantage to preoperative radiation and that is its detrimental effect on wound healing. Some groups have used an intraoperative or postoperative boost dose of radiation to the resection bed if there are concerns that margins are involved.

Figure 108-9. Wide excision involves removal of the tumor with a margin of normal tissue. If necessary, major vascular structures or nerves may be resected.

Figure 108-10. **A:** Radical amputations for extremity sarcomas include one joint above the most proximal extent of tumor. Now largely of historic interest, tumors of the proximal thigh or buttock were previously routinely treated with hemipelvectomy. **B:** While limb-sparing procedures are now done whenever possible, amputation may be necessary for certain cases. This 60-year-old woman had high-grade angiosarcoma of the right leg with extensive satellite metastases extending above her knee. She required above-knee amputation.

Table 108-4 Complications of Treatment for Extremity Sarcoma

Treatment Modality	Complication	Comment
Surgical resection	Wound complications Seroma/hematoma Inadvertent damage to neurovascular structures	
Radiation	Fibrosis Edema Pathologic fracture Delayed wound healing/wound complications	Prophylactic intramedullary nailing may be considered Greater incidence with preoperative radiation treatment
Chemotherapy Doxorubicin	Myelosuppression Cardiotoxicity (arrhythmia, heart failure)	Baseline echocardiogram and/or MUGA are mandatory Combination therapy may have additive toxicities Alopecia and nausea/vomiting are common side effects of these chemotherapy agents
Ifosfamide	Myelosuppression Neurotoxicity Nephrotoxicity	

Increasing data support the use of resection alone for selected patients; those who have small (<5 cm), low-grade tumors seem to have acceptable local control and excellent long-term survival without radiation if wide margins are obtained at the time of resection.^{68,69} Most patients undergoing surgical excision may be candidates for additional radiation therapy because of high risk for recurrence, though its role in lower- or intermediate-risk patients is somewhat undefined, and the so-called therapeutic ratio of risk and benefits to radiation treatment must be carefully considered. Validated prognostic tools may be helpful for individual patients weighing the benefits of available treatment options. Kattan et al.⁷⁰ developed a nomogram to help better predict individual risk for 12-year disease-specific mortality in sarcoma patients using multiple prognostic factors simultaneously.

For extremity sarcomas, the importance of pathologically negative margins must be emphasized. While differing widths of margins have been called “optimal,” it is generally agreed that 1 to 2 cm are adequate, but that microscopically clear margins may be sufficient. Involved margins, along with age, recurrent presentation, and fibrosarcoma or MPNST subtypes, significantly increases the risk of local recurrence.^{3,71} Patients presenting with involved margins following the index operation should be offered resection in order to obtain surgical clearance of margins. Several studies have shown no compromise in survival if complete resection is achieved with a second operation.⁷² Interestingly, it is unclear if local recurrence predisposes to subsequent distant metastasis or if margin status is merely a proxy for aggressive disease.^{71,73}

Since the main cause of death in patients with soft tissue sarcoma is distant metastatic disease, continued efforts have been made to develop effective systemic therapies.^{5,74} Postoperative adjuvant chemotherapy has been controversial because risk of adverse toxic effects may not be outweighed by the relatively low response rates and lack of durable results. The histologic subtypes of sarcoma vary in their responsiveness to chemotherapy. For example, osteogenic sarcoma, rhabdomyosarcoma, and Ewing sarcoma (the “pediatric” sarcomas) have had high rates of success with multimodality treatments including adjuvant chemotherapy.⁵⁹ Unfortunately, most randomized trials are underpowered to detect modest differences in survival and promising response rates reported in smaller nonrandomized clinical trials are not duplicated in subsequent larger randomized trials. In general, adjuvant chemotherapy is not ever indicated for patients with low-grade sarcomas and patients with small sarcomas of higher grades. Initial interest in adjuvant chemotherapy for extremity soft tissue sarcoma was piqued by a randomized trial reported by Rosenberg et al.⁷⁵ which demonstrated an improvement in disease-free and overall survival with adjuvant doxorubicin, cyclophosphamide, and high-dose methotrexate. After a longer follow-up period (median follow-up 7.1 years), however, both disease-free and overall survival were not statistically significant.⁷⁶

Over the years, single agents as well as combination chemotherapy regimens have been used in the adjuvant treatment of soft tissue sarcomas. Two of the more active agents include doxorubicin and ifosfamide. However, multiple randomized trials of postoperative chemotherapy have not demonstrated an improvement in disease-free or overall survival with intermediate or long-term follow-up though there was a trend toward chemotherapy in many studies.^{59,77–79} The Sarcoma Meta-analysis Collaboration evaluated the effect of adjuvant doxorubicin-based chemotherapy in 1,568 patients from 14 trials.⁸⁰ Although the time to local and distant recurrences, as well as recurrence-free survival, were significantly better in the treatment group, an overall survival advantage was not seen (HR 0.89, $p = 0.12$). Because of the rarity of disease and heterogeneity of tumor characteristics, most studies are too small to provide adequate power for testing responses in specific histologic subtypes. In general, many

regimens have combined two of the most active agents, doxorubicin (or other anthracycline) and ifosfamide, and results from a randomized trial did show improved disease-free survival and overall survival; distant relapse rates were not different however.⁸¹ Outside of clinical trials, adriamycin and ifosfamide combination therapy is commonly used for high-risk, primary extremity and truncal sarcomas in the adjuvant setting. Newer regimens with promising results include the combination of gemcitabine and docetaxel which was initially discovered to be active in heavily pretreated uterine leiomyosarcomas and is currently being considered for use in that subtype as well as in high-grade undifferentiated pleomorphic sarcomas and other high-risk subtypes.⁸²⁻⁸⁴ A phase II study comparing adriamycin and ifosfamide to the combination of gemcitabine and docetaxel found that the latter regimen had a slightly lower hospitalization rate and trends toward longer disease-free survival rates.⁸⁵

Even with advances in systemic chemotherapy and targeted agents, data supporting greatly improved overall survival rates are sparse, especially in the adjuvant setting. For advanced tumors, treatments with single agents or combination regimens such as dacarbazine, doxorubicin, epirubicin, ifosfamide, gemcitabine, docetaxel, temozolomide, trabectedin, and eribulin have been trialed extensively. Newer targeted therapies have shown some promise in certain histologic subtypes. For example, tyrosine kinase inhibitor (TKI) agents such as pazopanib, imatinib, sorafenib, and sunitinib have shown efficacy in multiple subtypes after initial success with GISTs. The class of mTOR inhibitors (sirolimus, temsirolimus, and everolimus) has demonstrated promise for perivascular epithelioid cell tumors (PEComas), lymphangiomyomatosis, and angiomyolipomas.

One potential advantage of upfront systemic chemotherapy is the ability to assess tumor response in situ. By seeing whether the tumor responds to the chemotherapy, both radiologically and pathologically, it may be possible to spare patients prolonged therapy if they have not shown a response, or to continue therapy postoperatively if there is response. However, data from a trial of preoperative doxorubicin and ifosfamide-based chemotherapy conducted by the European Organisation for Research and Treatment of Cancer (EORTC) and the National Cancer Institute of Canada did not demonstrate any survival benefit compared to surgery alone.⁸⁶ Some agents such as gemcitabine may have chemosensitizing properties,⁸⁷ making preoperative chemoradiation strategies attractive. Based on current evidence, neoadjuvant chemoradiation, either concurrent or sequential, should only be offered to selected high-risk patients on clinical protocol.⁸⁸ It is important to follow patients on neoadjuvant therapy closely since tumor progression is expected to be seen in approximately 30% of patients.^{89,90}

Commonly used measures of radiologic response to treatment may not be good surrogate endpoints for treatment response.³⁸ The pathologic correlations of treatment-induced necrosis or histologic response to therapy with clinical outcomes have also not been well defined in soft tissue sarcoma.⁹¹ Some patients who have a clinical or pathologic response to chemotherapy may have improved local control and decreased distant disease-free survival, but no overall survival advantage.⁹² In other cases, lack of measurable response did not seem to predict significant differences in event-free endpoints.⁸⁹ These issues must be carefully considered in the design of future trials.

Alternative approaches to standard systemic therapy have been attempted with limited success. For example, preoperative radiation therapy in combination with intra-arterial doxorubicin chemotherapy initially showed good local control, but results could not be duplicated in subsequent randomized trials and treatments were associated with high morbidity.^{93,94} Regional chemotherapy administered via hyperthermic isolated limb perfusion has been attempted for advanced extremity sarcomas. Extracorporeal circulation allows the delivery of drug concentrations 10 to 20 times higher than with systemic delivery and a European study showed a limb-salvage rate of 71% for unresectable extremity sarcomas using melphalan and tumor necrosis factor- α .^{95,96} However, this technique is uncommonly used in the United States and usually reserved for highly selected patient populations.

RETROPERITONEAL AND INTRA-ABDOMINAL SARCOMAS

Management of intra-abdominal (visceral) and retroperitoneal sarcomas deserves special consideration since specific anatomic location may dictate workup and subsequent management. The grouping of visceral sarcomas generally includes tumors of the gastrointestinal tract and gynecologic organs, and less commonly, genitourinary organs. Location often precludes early diagnosis, unless the mass is found incidentally. Though some patients have noted increased abdominal girth, an abdominal mass can be appreciated with focused physical examination, but it is uncommonly the presenting complaint. Typically, vague symptoms of mass effect intra-abdominally trigger medical evaluation. Neurovascular symptoms related to compression or invasion can occur and manifest as paresthesia, dysesthesia,

weakness, and swelling or varicosities in the lower extremities.

Complete history and physical examination should exclude signs and symptoms of lymphoma (e.g., B-symptoms such as fevers and night sweats) and presence of scrotal masses concerning for testes cancer. Serum laboratory testing can be helpful if lymphoma (e.g., elevated lactate dehydrogenase [LDH]), germ-cell tumors (e.g., elevated beta-human chorionic gonadotropin (B-HCG) or alpha-fetoprotein [AFP]), or adrenal tumors (i.e., cortisol levels or adrenocorticotrophic hormone [ACTH]) are in the differential diagnosis. High-quality cross-sectional imaging with CT or MRI is critical for diagnosis and treatment planning. Use of oral and intravenous contrast defines extent of primary disease and the relationship of the tumor to nearby structures. Chest imaging should be obtained to assess for presence of pulmonary metastases. Hepatic involvement is the second most common site of distant spread in intra-abdominal and retroperitoneal sarcomas, so a CT scan that includes the proper contrast phasing for examination of the liver should be done.

4 For large tumors, preoperative image-guided biopsy can almost always be performed by experienced interventional radiologists (Fig. 108-11). However, preoperative biopsy is not mandatory^{5,97} if management would not be altered by findings. Use of biopsy is reserved for cases in which a diagnosis of sarcoma is in question or if neoadjuvant approaches are being considered for large, high-grade lesions or lesions which are locally advanced and potentially unresectable. Complete resection is the treatment of choice for intra-abdominal (visceral) and retroperitoneal sarcomas whenever possible. Only complete resection is associated with long-term survival benefit, with retroperitoneal liposarcomas being a possible exception.^{98,99} For retroperitoneal sarcomas, median survival for those with an incomplete resection is similar to those who were observed (unresectable)¹⁰⁰ (Fig. 108-12). In general, incomplete resection should only be considered for palliation of intractable symptoms. While successful palliation may be achieved in carefully selected patients, aggressive tumor biology limits the ability to maintain sustained relief of symptoms.¹⁰¹

In order to attain complete removal of the sarcoma, en bloc resection of nearby structures should be considered when necessary. Resectability is more a function of location than of size, grade, or histologic subtype. Common reasons for unresectability include distant metastasis, peritoneal metastasis, extensive multifocality, and prohibitive vascular involvement. Though sarcomas do not uniformly invade other structures, involvement of vascular structures or mesentery (mesocolon) may lead to resection of solid organs or bowel that may not be directly involved. When nephrectomy may be necessary, it is important to assess bilateral renal function with preoperative contrast scanning. Concomitant nephrectomy, when necessary, is associated with comparable outcomes for retroperitoneal sarcomas overall.¹⁰² Commonly resected organs include the following: kidney, colon, adrenal gland, pancreas, and spleen.¹⁰³ For tumors located in the pelvis, it may be necessary to perform en bloc resection of the colon/rectum, bladder, and uterus. When vascular structures limit complete resection of tumor, resection with ligation or reconstruction of vessels must be considered if technically feasible (Fig. 108-13).

Even when surgical resection is possible and complete gross resection is achieved, margin status is often compromised by constraints of visceral anatomy. A transperitoneal approach allows for excellent exposure and facilitates en bloc resection of with early control of the vascular supply to the tumor. Analyses of relatively aggressive approaches to resection include complete compartmental resections and liberal use of en bloc visceral resection shows better local control, but high-grade tumors tend to recur systemically. Proper patient selection for so-called “aggressive resection” needs to be weighed against the natural history of sarcoma.^{104–106} It is generally agreed that the best chance for curative intent resection is at the time of first operation. Complex multivisceral operations should be referred to higher-volume centers with experienced sarcoma surgeons when possible.

Figure 108-11. Biopsy can be helpful in the workup of retroperitoneal masses. **A:** CT scan shows a retroperitoneal mass encasing the IVC and aorta. **B:** Image-guided biopsy is demonstrated here. Pathology confirmed a diagnosis of large B-cell lymphoma.

Even with aggressive surgical management, local recurrence rates range from 40% to 70% for high-grade tumors.^{13,107} Unlike extremity sarcomas, local progression is associated with decreased survival. Difficulty obtaining negative margins and high recurrence rates support a role for carefully selected multimodality treatments. The benefits of radiation for extremity sarcomas have not been similarly appreciated for retroperitoneal sarcomas and no improvement in disease-free intervals have been noted.¹⁰⁸ Large field sizes and the dose-limiting toxicity of abdominal viscera limit the utility of postoperative radiation, and preoperative radiation warrants consideration. The major advantage of preoperative radiation is the displacement of small bowel and other structures by the in situ tumor. Similar to preoperative radiation for extremity tumors, a possible advantage in the abdomen/retroperitoneum is that the radiation may prevent later seeding of tumor cells because radiation is administered to tumor and surrounding peritoneum. With the advent of conformal technology, or intensity-modulated radiation therapy (IMRT), further selective application of radiotherapy may be possible with minimal toxicity.^{109,110} The role of chemotherapy, either in the preoperative or postoperative setting, is unproven for intra-abdominal and retroperitoneal sarcomas.^{111,112} Several trials of postoperative adjuvant chemotherapy do not show any benefit for patients with retroperitoneal sarcoma, and in one series, treated patients fared worse than those not receiving chemotherapy.¹¹³ In one trial of an aggressive multimodality approach, there was an improvement in locoregional control but no overall survival advantage and significant toxicity from the chemotherapy and radiation therapy.¹¹⁴ Though some histologic subtypes, such as leiomyosarcoma, pleomorphic sarcoma, or myxoid/round cell liposarcoma, may be relatively more responsive to systemic treatments, a paucity of data exist to guide appropriate use of therapy. Randomized controlled trials have been notoriously difficult to accrue patients to.

Special consideration is also given to complete resection with functional preservation in head and neck sarcomas and genitourinary sarcomas. As is true of sarcomas in other anatomic locations, histologic grade and size adversely affect prognosis for head and neck sarcomas.¹¹⁵ Resections with negative margins may not require adjuvant radiotherapy treatments. Similarly, grade, size, location, and histologic subtype similarly predict disease-specific survival for genitourinary sarcomas.¹¹⁶ Regional relapse is influenced by margin status so radical resections are necessary. Unfortunately, recurrences are not uncommon and may be difficult to control due to anatomic location.

Figure 108-12. Kaplan–Meier plot of disease-specific survival for patients with retroperitoneal sarcomas treated at Memorial Sloan Kettering Cancer Center. Disease-specific survival is 103 months in patients who underwent complete resection of retroperitoneal sarcomas, compared to 18 months in those who had an incomplete resection or just observation. (From Lewis JJ, Leung D, Woodruff JM, et al. Retroperitoneal soft-tissue sarcoma: analysis of 500 patients treated and followed at a single institution. *Ann Surg* 1998;228(3):355–365.)

Figure 108-13. Inferior vena cava (IVC) leiomyosarcoma. **A:** CT scan demonstrates a 9.2- × 6.4- × 4.4-cm mass within the lumen of the retrohepatic IVC. **B:** Photograph of the gross specimen. Cross-sectional view from the superior aspect of the specimen demonstrates the extensive filling of the lumen with multilobulated tumor. **C:** Photomicrograph demonstrating intraluminal high-grade leiomyosarcoma with nuclear atypia and pleomorphism. Uninvolved smooth muscle of the IVC is shown (right lower quadrant). (Courtesy of Jason Carvalho, MD and David R. Lucas, MD, University of Michigan, Ann Arbor, MI.)

RECURRENT OR METASTATIC DISEASE

About two-thirds of soft tissue sarcoma recurrences occur in the first 2 years after diagnosis and treatment, though recurrences may be seen at any time.¹¹⁷ Recurrences may be classified as locoregional or distant. Though no standardized follow-up regimens exist, routine history and physical

examination (clinical follow-up) and interval chest imaging are recommended for the first 2 to 3 years. Site-specific imaging guidelines are less clear. Directed cross-sectional imaging studies are helpful if location of tumor precludes early detection of recurrence on clinical evaluation alone. Of course, the choice of imaging study depends on availability, cost, and anatomic site being examined. MRI of the extremity or trunk can help detect locoregional recurrences when they are relatively small. CT scans may be useful for detection of intra-abdominal or retroperitoneal recurrences which would otherwise be undetectable. However, there is no evidence that earlier detection improves survival for retroperitoneal sarcomas,¹⁰⁰ so a less aggressive imaging schedule may be appropriate.

If chest radiography is used, abnormal findings should be followed with a CT scan of the chest. Low-grade lesions infrequently metastasize in the absence of local recurrence, though can recur locally up to 20 years after original resection. For high-grade lesions, surveillance should be directed toward detecting recurrence and metastatic disease. Patients with locally recurrent or even metastatic sarcomas can be considered for surgical resection if tumor biology supports potential cure or effective palliation with removal of known disease. Recurrent disease, especially within the abdomen or retroperitoneum, becomes more difficult to treat with each recurrence.¹¹⁷

If a recurrence is suspected, a biopsy should be performed to confirm diagnosis and review histologic subtype as well as tumor grade, with reference to the original tumor if possible. In the absence of distant disease, an aggressive surgical approach is warranted with the goal being the same as with a primary sarcoma – control of the tumor and preservation of as much function as possible. For patients who were initially treated with surgery alone and who failed locally, multimodality treatment with repeat resection, radiation, and sometimes chemotherapy is associated with survival rates close to those of previously untreated patients.^{118–120} Independent predictors of survival in patients with locally recurrent extremity soft tissue sarcomas include histologic grade, size of recurrent disease, and recurrence-free interval.¹²¹

The most common site of distant metastatic disease is the lung, and its presence is not detectable by symptoms. Again, CT is the preferred imaging modality, though its very high sensitivity for detecting pulmonary nodules as small as 2 mm decreases its specificity.^{122,123} Occasional patients have liver, bone, or central nervous system metastases though these sites of disease are relatively uncommon. Once diagnosed, metastatic disease is best approached with systemic chemotherapy, either as a single agent or with combination treatments. Pulmonary metastases are the most common form of distant disease, and metastasectomy in carefully selected patients seems to improve outcomes. Taking patient selection into account, resection of pulmonary metastases in combination with radiation and/or chemotherapy, may improve outcomes compared to resection alone^{124,125} (Fig. 108-14).

Figure 108-14. Kaplan–Meier plot of disease-specific survival for patients with pulmonary metastases treated at Memorial Sloan Kettering Cancer Center. Patients treated with complete resection had a median survival of 33 months. Patients who underwent incomplete resection or who did not undergo resection had median survival of 16 months and 11 months, respectively. (From Billingsley KG, Burt ME, Jara E, et al. Pulmonary metastases from soft tissue sarcoma: analysis of patterns of diseases and postmetastasis survival. *Ann Surg* 1999;229(5):602–610.)

GASTROINTESTINAL STROMAL TUMORS

Another subtype of sarcoma which deserves separate consideration is GIST. Prior to modern molecular

diagnostic techniques, these tumors were likely to have been considered leiomyosarcomas based on histologic features.¹³ It is now known that GISTs are differentiated from GI leiomyosarcoma based on lack of well-differentiated smooth muscle cells. GISTs are composed of more primitive mesenchymal cells and originate from the interstitial cell of Cajal, which functions within the GI autonomic nervous system. Immunohistologic diagnosis is made via expression of KIT (CD 117) cellular markers. KIT overexpression is usually related to mutations in the *KIT* gene, although *PDGFR-α* mutations can also result in KIT overexpression in approximately 3% to 5% of GIST. KIT-negative GISTs have been reported, though tumor genotyping should be done to either *KIT* or *PDGFR-α* mutations even with negative immunohistochemistry for KIT.¹²⁶

The *KIT* proto-oncogene encodes for KIT protein, a transmembrane glycoprotein receptor with an intracellular tyrosine kinase domain. Binding of the KIT ligand induces dimerization and autophosphorylation of KIT, activating a cascade of intracellular signaling which results in cell proliferation and tumorigenesis. A gain of function mutation in KIT occurs in up to 90% of GIST¹²⁷ and results in ligand-independent (constitutive) activation of tyrosine kinase function.¹²⁸ KIT mutation is found in 90% of GIST and the most frequent sites of mutation are found in exon 11 (70%) or exon 9 (10%), whereas rare mutations are found in exon 13 or exon 17.¹²⁹ Mutation status may affect prognosis, and testing has become more routine in the evaluation of GIST.

Swedish epidemiologic data estimates 14.5 cases per million, which translates to an annual US incidence of 4,000 to 5,000 new cases of GIST per year.¹³⁰ GISTs are largely sporadic, but they have been seen in association with hereditary syndromes such as von Recklinghausen disease and Carney triad, and familial germline mutations have been identified. Clinical presentation can be indolent – most patients have nonspecific symptoms such as nausea, emesis, or abdominal discomfort. Infrequently, GIST can rupture or bleed, leading to a more emergent presentation. GISTs are most commonly found in the stomach (50% to 60%), with 30% to 40% of tumors in the small bowel, 5% in the colon or rectum, and 5% in the esophagus. Rarely, GISTs develop within the mesentery, omentum, or retroperitoneum. Most GISTs are found in adults over the age of 40, with a median age of 60 years. Tumors found in children or young adults are considered a separate entity since pediatric GISTs have a more epithelioid histology and wild-type KIT or *PDGFR-α* genotype.¹³¹

Complete surgical resection is the treatment of choice for GIST, but recurrences are common and 5-year survival following resection of a localized tumor is approximately 50%.¹³² Recurrences are common and thought to occur at 18 to 24 months from the time of the index operation. Lymph node dissection is not warranted because GIST very rarely metastasizes to regional nodes. Treatment of GIST was revolutionized with the development of imatinib mesylate (Gleevec), a selective tyrosine kinase inhibitor, representative of the emerging paradigm of molecularly targeted therapies. The proof of concept for this treatment paradigm was demonstrated in 2000 when a patient with diffuse metastatic disease achieved a near-complete metabolic response¹³³ on PET and with 75% reduction in tumor size at 8 months and histologic evidence of myxoid degeneration and lack of mitotic activity. Contemporary use of imatinib in patients with metastatic GIST is considered appropriate first-line treatment of metastatic disease (Fig. 108-15).

For patients who present with localized tumors, resection remains the mainstay of treatment. Interestingly, emerging evidence suggests that incidentally discovered, very small GISTs (<2 cm) may be successfully managed expectantly.

Figure 108-15. ¹⁸FDG-PET scan showing response of metastatic GIST to imatinib mesylate. This patient presented with primary disease in the small bowel and synchronous metastatic disease in the liver. The scan at presentation (**left**) compared to the one obtained after 3 weeks of therapy (**right**) shows decrease in size of tumors and decreased ¹⁸FDG uptake in both the small bowel and liver tumors consistent with a good response to imatinib. The patient eventually went on to complete surgical resection. (From Gold JS, Dematteo RP. Combined surgical and molecular therapy: the gastrointestinal stromal tumor model. *Ann Surg* 2006; 244(2):176–184.)

5 The use of imatinib in the adjuvant setting has been informed by a number of clinical trials. Mutation status is predictive of treatment success; *KIT* exon 11 mutations are associated with better response rates and survival endpoints than exon 9 mutations and wild-type GISTs. Because of high rates (> 50%) of recurrence or metastasis following resection, at least 3 years of imatinib is recommended for high-risk tumors, including tumors which are greater than 5 to 10 cm in size or contain more than 5 mitoses per 50 HPFs. Risk stratification must be approached with care; other factors which need to be considered include location of tumor and mutation status. It is reasonable to consider the use of imatinib for large or borderline resectable lesions prior to surgical resection. Most of these cases require continued treatment after resection given the high risk of recurrence or metastasis. Second- and third-line (and beyond) therapies are available for drug-resistant disease, but as expected, responses following failure of first-line therapy are highly variable.

DESMOID TUMORS/DESMOID FIBROMATOSIS

Desmoid tumors warrant separate notation in the discussion of soft tissue tumors because of their distinct biologic behavior.^{15,134} Desmoid tumors, or aggressive deep-seated fibromatosis, are part of a rare group of fibrous tissue proliferations which have no propensity for metastasis but tend to be locally aggressive. The natural history of desmoid tumors is not well defined and poorly understood. Clinical behavior and therefore, recommended treatments, are often dictated by anatomic site. Location of tumors can limit therapeutic options and result in significant morbidity with or without surgical resection.

Desmoid tumors are uncommon with an estimated incidence rate of 2 to 4 cases per million per year. The median age of diagnosis is 35, range 16 to 79 years. Desmoids are slightly more common in women than men. Desmoid tumors are classically described as an abdominal wall tumor, seen in young women during the postpartum period.¹³⁵ However, desmoids can occur at any site in the body and three main anatomic sites are described: (1) trunk or extremity, (2) abdominal wall, and (3) intra-abdominal (bowel and mesentery). Fibromatosis is usually seen sporadically, but can be associated with FAP.

Desmoids are characterized by a monoclonal fibroblastic proliferation arising from muscular or aponeurotic structures. On gross examination, the tumors appear firm and smooth, with a surrounding pseudocapsule. However, microscopically, the tumor characteristically extends beyond this pseudocapsule, with fibrous septae of tumor extending radially. Desmoid tumors had previously been classified as an unchecked reactive process rather than a neoplastic process, but uniform patterns of X-chromosome inactivation seems to confirm tumors of clonal composition.¹³⁶ There appears to be an increased estrogen receptor- β , but not estrogen receptor- α , expression in 80% of desmoid specimens.¹³⁷ These findings lend some support for the treatment of tumors with adjuvant agents such as tamoxifen.

Tumors tend to be located deep in the muscles or along fascial planes, such as at a point of muscular insertion. Patients will usually present with a greater than 5 cm, localized, firm mass with an indolent pattern of growth, which can be minimally painful. Intra-abdominal presentations can be associated with mass effect, intestinal obstruction, or mucosal ischemia. Desmoid tumors are notoriously infiltrative, and microscopically involved margins are seen in a significant number of patients.

Complete resection is considered the best course of treatment, though resection is sometimes constrained by anatomic boundaries. For intra-abdominal tumors, extensive association with the mesentery limits the extent of resection and could predispose to significant morbidity and ultimately, mortality due to bowel involvement. Resection of large abdominal wall tumors often requires prosthetic reconstruction of the resulting defect. Ability to accomplish complete resection at the first attempt defines likelihood of recurrence, so it is important to have a sufficient preoperative suspicion of fibromatosis and to be circumspect in surgical technique. Positive margins do not inevitably lead to recurrent disease, just as patients with a complete microscopic resection are often found to have local recurrences.¹³⁸ Given the natural history of desmoid fibromatosis, emerging management strategies for selected tumors which are small, asymptomatic, and located such that growth would not change ability

to resect or lead to functional limitations are increasingly discussed. Surveillance plans must be adhered to and progression prompts resection or other treatment.

There are no data to support the use of radiation therapy in the adjuvant setting following a complete surgical resection. The utility of radiation in the setting of positive resection margins is thought to be quite minimal given the difficulty in predicting risk of recurrence in these patients. A number of systemic treatment regimens have been used in the past and in present practice with varying results.

BONE SARCOMAS

A variety of primary bone tumors are well described ([Table 108-5](#)). The vast majorities (>70%) of bone malignancies represent metastasis from another site or are of hematologic origin (lymphoma or myeloma). Primary bone cancers, however, are an extremely rare type of cancer, with only an estimated 3,300 new cases in 2016.¹ The three main types of bone sarcomas are osteosarcoma (which arises from bone), chondrosarcoma (which arises from cartilage), and Ewing sarcoma (which have an undefined origin). As with soft tissue sarcomas, a GTNM staging system is used by the AJCC⁴⁵ ([Table 108-6](#)). Modern multimodality treatment approaches have been associated with excellent outcomes, including possibility of cure for many osteosarcoma cases.

Table 108-5 Histologic Classification of Bone Tumors

Tissue Category	Benign Tumor	Malignant Tumor (Bone Sarcoma)
Bone	Osteoid osteoma	Osteogenic sarcoma
	Osteoblastoma	Parosteal osteogenic sarcoma
Cartilage	Osteochondroma	Periosteal osteogenic sarcoma
	Endochondroma	Chondrosarcoma
	Chondroblastoma	Mesenchymal chondrosarcoma
Fibrous lesions	Benign fibrous histiocyoma	Malignant fibrous histiocyoma
	Giant cell tumor	Adamantinoma
	Fibrous dysplasia	Fibrosarcoma
Vascular	Aneurysmal bone cyst	Angiosarcoma
Other	Glomus tumor	Hemangiopericytoma
		Ewing sarcoma

Table 108-6 American Joint Commission on Cancer (AJCC): GTNM Classification and Stage Grouping of Bone Sarcomas

Classification	Description
Tumor Grade	
GX	Grade cannot be assessed
G1	Well differentiated (low grade)
G2	Moderately well differentiated (low grade)
G3	Poorly differentiated
G4	Undifferentiated
Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor ≤8 cm in greatest dimension
T2	Tumor >8 cm in greatest dimension
T3	Discontinuous tumors in the primary bone site
Lymph Node Involvement	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
Distant Metastasis	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Lung
M1b	Other sites
Stage Grouping	
Stage IA	G1-2, T1, N0, M0
Stage IB	G1-2, T2, N0, M0
Stage IIA	G3-4, T1, N0, M0
Stage IIB	G3-4, T2, N0, M0
Stage III	Any G, T3, N0, M0
Stage IVA	Any G, any T, N0, M1a
Stage IVB	Any G, any T, N1, any M
	Any G, any T, any N, M1b

Osteosarcomas are the most common primary bone tumor. Osteosarcomas occur most commonly around the knee, either in the distal femur or proximal tibia, but they can be encountered in any bone (Table 108-7). Osteosarcomas originate in the metaphyseal ends of the involved bone. While there are eleven known variants of osteosarcoma, classic osteosarcoma accounts for nearly 80% of incident cases. They are commonly seen in children and young adults. Other important variants include osteosarcoma associated with Paget disease,¹³⁹ which corresponds to a later peak in incidence at 60 years of age. Other well-described etiologies of osteosarcoma include prior radiation or history of retinoblastoma.¹⁴⁰ Classic osteosarcomas are of intramedullary origin and are high grade. Osteosarcoma patients are at high risk for metastatic disease; metastases to the lung are the most common, though bony metastases are not uncommon. Low-grade variants do exist and these less aggressive tumors are usually parosteal or periosteal in location. Elevated serum alkaline phosphatase and lactate dehydrogenase is associated with reduced disease-free survival and overall survival rates.

Table 108-7 Distribution of Anatomic Locations of Osteosarcoma

Anatomic Site	Percentage (%)
Lower extremity	77.6
Upper extremity	12.9
Pelvis	6.0
Shoulder	2.6
Vertebrae	0.8

Adapted from Eilber FR, Guiliano AE, Huth J, et al. High-grade soft-tissue sarcomas of the extremity: UCLA experience with limb salvage. *Prog Clin Biol Res* 1985;201:59-74.

Chondrosarcomas are typically classified as either (1) primary or central tumors arising from previously normal-appearing bone, or (2) secondary or peripheral tumors that develop from pre-existing benign cartilage lesions.^{141,142} The secondary or peripheral lesions are usually low grade and infrequently metastasize. Chondrosarcomas are usually seen in middle-aged or elderly people, though can be seen at any age. Ewing sarcomas are broadly considered a family of small round cell neoplasms and include the following subtypes: Ewing sarcoma, primitive neuroectodermal tumor (PNET), and extrasosseous Ewing sarcoma. Most Ewing sarcomas occur in adolescents and young adults but can be seen in older individuals. These tumors may arise in soft tissues as well as bone, and are most commonly seen in the femur, pelvic bones, and chest wall (Askin tumor).

CLINICAL PRESENTATION

A painful mass is the most common presenting complaint with an extremity osteosarcoma, though symptoms of chondrosarcoma may be quite mild. Tumor location in the axial skeleton may also be associated with a more insidious presentation. Limitation of motion is often present when the tumor arises in proximity to a joint. Patients occasionally present with a pathologic fracture of the involved bone. Plain radiographs of the affected area often suggest a diagnosis. High-grade osteosarcomas lead to rapid destruction of bone evidenced by cortical destruction and demonstrate periosteal reaction with new bone formation; an extensive, poorly defined destructive bony lesion, often with an extrasosseous component is often seen (Fig. 108-16). Ewing sarcomas have a classic “onion skin” periosteal reaction and underlying bone often appears mottled. Primary or central chondrosarcomas show cortical destruction and calcification. Further radiologic evaluation with MRI (or CT scan) provides excellent detail of the anatomic extent of tumor and aids operative planning. Chest imaging should be used to determine if there is metastatic disease. Evaluation with radionuclide bone scanning and/or PET scans may also be useful depending on clinical context.

After the radiologic evaluation establishes the extent of the bony lesion, diagnostic biopsy should be performed. Either CNB or open biopsy techniques can be used. Placement of the incision should be carefully planned to avoid jeopardizing subsequent options for a limb-sparing procedure. Consideration should also be given to stabilization techniques if there is risk of pathologic fracture during treatment.

Cytogenetic analysis for evaluation of the t(11;22) translocation should be done if Ewing sarcoma is suspected.¹³ Presenting features associated with poor prognosis in Ewing sarcoma include elevated serum lactate dehydrogenase levels, fever, anemia, large tumor volume, mutation in p53 or deletion of p16/p14ARF, and pelvic location. Most patients have at least micrometastatic disease at presentation, and bone marrow biopsy can be considered because it is a common site of distant disease.

TREATMENT

6 Standard treatment for Ewing sarcoma involves combination chemotherapy, followed by surgical resection. Regimens have evolved over time and currently involve some combination (or all) of the following agents: ifosfamide, cyclophosphamide, etoposide, doxorubicin, and vincristine.¹⁴³ Investigations continue to define the trade-offs between survival benefit and toxicity of high-dose combination chemotherapy.¹⁴⁴ Adjuvant radiation can be considered or used as definitive treatment in some cases. Most patients will receive additional chemotherapy in the postoperative period as well. The aggressive use of multimodality therapy has led to excellent outcomes for patients with localized disease over time. Five-year survival rates have improved from 44% in the 1970s to 68% in the 1990s. Even outcomes with advanced disease at presentation has improved dramatically, increasing from 16% to 39% over the same time period.¹⁴⁵

Figure 108-16. Plain radiograph of the femur showing a high-grade osteosarcoma. The tumor is an ill-defined destructive lesion with an extensive soft tissue involvement. Codman triangles (*arrows*) indicate periosteal reaction, which are characteristic, but not pathognomonic, of osteosarcoma.

Surgical resection is the definitive treatment for most chondrosarcomas (Fig. 108-17). Intracompartmental lesions can be considered for intralesional resection with wide margins. Radiation can be considered as an adjuvant therapy, but chemotherapy is generally not very effective. If lesions are unresectable, radiation may be considered as a possible definitive treatment modality.

Historically, patients with clinically localized osteosarcoma treated by surgery alone had a 5-year survival rate of approximately 20%. Adjuvant systemic chemotherapy after surgery has greatly improved that figure to 55% to 70% in most randomized trials.^{146,147} Several agents have shown to be active and regimens have used differing combinations of those agents – doxorubicin, cisplatin, ifosfamide, and high-dose methotrexate. Disease relapse should be treated with further chemotherapy and repeat resection if possible. Progressive disease carries a poor prognosis.

Extremity osteosarcomas are ideally treated with limb-sparing approaches when possible to maximize functional outcomes. Limb-sparing operations include complete removal of the affected bone and soft tissues. A variety of reconstructive techniques are available after resection of an extremity osteosarcoma. Autografts (such as vascularized or nonvascularized fibular grafts), cadaver allografts, and sophisticated endoprostheses can be used. Because the osteosarcoma population includes many children who continue to grow, modular prostheses that can periodically be expanded are increasingly being used.

Figure 108-17. Chondrosarcoma recurrence. A 60-year-old man had previously undergone resection of a low-grade chondrosarcoma of the left pelvis, necessitating resection of the left iliac bone. After many local bony recurrences, he was found to have an extraskeletal site of disease. On the CT scan, adjacent to the remaining bone, there is a 4.4- × 3.6-cm soft tissue mass (arrow), which contains dystrophic calcifications. Recurrent disease was completely resected.

Chapter 109

Plastic and Reconstructive Surgery

Christian J. Vercler, David L. Brown, Steven R. Buchman, Paul S. Cederna, Kevin C. Chung, Jeffrey H. Kozlow, William M. Kuzon, Jr., Adeyiza O. Momoh, and Edwin G. Wilkins

Key Points

- 1 A variety of operative procedures have been described for breast reconstruction following mastectomy. These approaches can be categorized as implant-based, autogenous (natural) tissue, and “hybrid” procedures.
- 2 Currently, the most commonly performed of these procedures are based on the lower abdominal soft tissue.
- 3 The absolute indications for replantation are (a) thumb amputation, (b) multiple finger amputations, (c) pediatric population amputations, and (d) mid-hand, wrist, or distal forearm amputations.
- 4 Rigid skeletal fixation, revascularization using vein grafts, and immediate wound coverage are crucial factors in successful limb salvage.
- 5 Aesthetic surgery requires meticulous attention to detail, careful patient selection, rigorous procedural planning, and precise execution of technically challenging procedures.
- 6 Patients who smoke are at a significantly increased risk for developing postoperative complications, including skin-flap necrosis, infection, or wound dehiscence; and are consequently instructed to quit prior to undergoing elective aesthetic surgery.
- 7 A cleft lip deformity can be bilateral or unilateral and is considered complete if it extends into the nose and incomplete if it does not. The cleft lip can extend into the gum partially or completely through the alveolus, creating a bony defect. The cleft lip deformity affects the nose as well as the lip, and therefore both of these structures must be addressed in the reconstruction of the deformity.
- 8 Craniosynostosis is defined as the premature fusion of one or more of the cranial sutures. The child afflicted with craniosynostosis displays abnormalities in the size and shape of the cranial vault.

Plastic and reconstructive surgery can be defined as a discipline that addresses problem wounds using a diverse array of nonsurgical and, especially, surgical therapies. In this definition, the term *problem wounds* is taken in the broadest sense; plastic surgeons treat traumatic, congenital, developmental, and even psychological wounds. Perhaps it is this latter aspect of plastic surgery that most fully sets it apart from other surgical specialties:

We restore and make whole those parts which nature or ill fortune have taken away, not so much to delight the eye but to buoy up the spirit of the afflicted.

—Gaspere Tagliacozzi, 1597

In more concrete terms, plastic surgery is an approach to surgical problems. Plastic surgeons operate “from the top of the head to the tip of the toes,” and they envision themselves as surgical innovators. Plastic surgeons have been instrumental in the development of microvascular surgery, craniofacial surgery, head and neck reconstruction, nerve grafting, and even renal transplantation.¹ Although the field of plastic surgery can be arbitrarily divided into “cosmetic” surgery (surgery to improve the appearance of a normal phenotype) and “reconstructive” surgery (repair of damaged anatomy or an abnormal phenotype), in many circumstances, both functional reconstruction and aesthetic improvement are paramount. Plastic surgery is truly “general surgery,” with a broad and growing list of subspecialties (Table 109-1).

PRINCIPLES OF MANAGEMENT FOR PROBLEM WOUNDS

Regardless of the etiology or location of a wound, the principles of management are universal and can

be embodied by a straightforward algorithm:

1. Evaluate and, if possible, eliminate the factors contributing to the presence of the wound.
2. Control or optimize the wound prior to closure.
3. Close the wound using the simplest method, unless specific factors mitigate a more complex approach.

Although it is the nature of surgeons to focus on the technical details of operative procedures, the first two steps in this algorithm are most critical for the successful reconstruction of problem wounds. This algorithmic approach allows plastic surgeons to treat diabetic foot ulcers, infected sternotomy wounds, major defects after composite resection of the head and neck, pressure ulcers, lower extremity wounds after open tibial fractures, venous stasis ulcers, and other difficult defects with a high degree of success. *This rational approach is the core of plastic surgery.* In plastic surgery there is no one-to-one correlation between a surgical problem and a specific operation. There is no “right” way to reconstruct a given defect, and a spectrum of options must be considered for every reconstructive problem. Selecting the best option for a given patient is the challenge.

Evaluation of Problem Wounds

The evaluation of patients with difficult wounds is best approached using a systematic approach since wounds are rarely secondary to only one isolated cause. Evaluation of both local and systemic (or intrinsic and extrinsic) contributing factors within each portion of the work-up is critical. In the history, local factors of importance include the mechanism that resulted in the wound, symptoms such as pain or loss of function, the time course and progression of the wound, any previous nonsurgical or surgical treatments for the wound, and any history of previous injury, irradiation, malignancy, or other local factors that contributed to the presence of the wound. The history should also uncover systemic factors that impair wound healing, including immunosuppression (e.g., chemotherapy, immune deficiencies), medical conditions known to impair healing (e.g., diabetes, renal failure), medications (e.g., steroids, cyclosporin A), cigarette smoking, and general debility (e.g., nutritional deficiencies, old age).

COMPLICATIONS

Table 109-1 The Spectrum of Plastic Surgery

Aesthetic surgery
Burns: acute and reconstructive surgery
Craniofacial surgery
Cutaneous and soft tissue oncology
Hand and upper extremity surgery
Head and neck oncology
Microvascular surgery
Maxillofacial and orthognathic surgery
Peripheral nerve surgery
“General” reconstructive surgery
Face (ear, lip, nose, and eyelid)
Breast
Trunk
Lower extremity

The physical examination of patients with problem wounds should be focused on local and systemic signs that affect wound healing. For the wound itself, the location, size, depth, exposure of deep or vital structures, presence of necrotic material, presence of foreign bodies, or signs of any neoplastic processes should be carefully noted. The clinician often needs to consider bacterial colonization and acute/chronic infection as potential addressable causes. All open wounds will have bacterial colonization, but this by itself does not designate a wound as “infected.” The diagnosis of infection is contingent on the physical examination findings of local inflammation: erythema, pain, swelling, fluctuance, purulence, and loss of function. Physical examination should be the primary criterion for the diagnosis of local wound infection; surface swabs indicating the presence of pathogenic bacteria do not correlate with clinically significant infection.² In addition to the wound itself, surrounding tissue should be examined for signs of injury (e.g., actinic changes), previous irradiation, arterial or venous insufficiency, lymphedema, loss of sensation, and dermal thinning (e.g., aging, steroid therapy). For all wounds on an arm or leg, a careful

neurovascular examination for the entire limb is mandatory. In addition to the local examination, a focused systematic physical examination is mandatory in patients with problem wounds. Systemic signs of infection (e.g., fever, hypotension) are of particular importance. Obesity is a major risk factor that impairs wound healing. The general physical examination should focus on the systemic factors that affect wound healing as noted previously. [Table 109-2](#) lists some of the local and systemic factors that impair wound healing; history and physical examination are the principal modalities for diagnosing these problems.

Laboratory examinations can be invaluable in the management of problem wounds. However, laboratory tests are often misused in wound patients, and a rational, evidence-based approach is necessary to efficiently utilize this expensive resource. Again, the local–systemic paradigm is useful in determining which laboratory examinations are warranted.

For local evaluation, wound swabs can be valuable for surveillance of the flora contaminating a wound but should not be used as a trigger to initiate therapy for wound infection. Wound biopsy and quantitative bacteriology have proved valuable in the management of burns and chronic wounds and can provide both topical and systemic antibiotic sensitivities.^{3,4} Bacterial loads in excess of 10⁵/g tissue indicate contamination at a level that precludes skin graft take and jeopardizes wound closure of any kind. The use of quantitative cultures, however, is not justified for most acute or uncomplicated chronic wounds. In general, quantitative cultures are reserved for “high stakes” wounds, where a failure of closure on the initial attempt may leave an unreconstructable situation with grave consequences, such as amputation or death. Wound biopsies can be invaluable for diagnosing invasive burn wound infection and are preferred over quantitative culture for this purpose.⁵ The presence of bacteria in the deep dermis on biopsy is highly correlated with the risk of systemic sepsis in burn patients. Bone biopsy demonstrating bacteria within the bone is the gold standard test for making the diagnosis of osteomyelitis. Standard radiographs are most useful for diagnosing and delineating acute fractures and are much less useful in the setting of chronic, open wounds. Ultrasound, computed tomography (CT) scan, or magnetic resonance imaging (MRI) may be useful for delineating fluid collections, necrotic tissue, or inflammation in selected circumstances. In contrast, radionuclide bone scans have little role to play in patients with open wounds or fractures. In the face of an open wound or recent fracture, a “hot” bone scan (even a triple-phase bone scan) is not specific for osteomyelitis and has little value. Therefore, obtaining bone scans in patients with suspected sternal osteomyelitis after recent midline sternotomy, in pressure sore patients with exposed bone, or in other patients with open wounds overlying exposed bone is unwarranted. Under these circumstances, bone biopsy is preferred for making a diagnosis of osteomyelitis and for determining the responsible pathogen; MRI is preferred for delineating the extent of bony involvement. Computed tomography angiography (CTA), magnetic resonance angiography (MRA), or standard angiography may be indicated if vascular insufficiency is suspected or if a free-tissue transfer is planned. The choice of modality depends on both patient and health system-based factors.

CLASSIFICATION

Table 109-2 Local and Systemic Factors That Affect Wound Management

Local Factors	Systemic Factors
Infection	Immune deficiencies
Local malignancy	Distant malignancy
Foreign bodies	Diabetes mellitus
Local toxins	Cigarette smoking
Radiation	Chemotherapeutic agents
Ischemia	Hereditary healing disorders
Venous insufficiency	Nutritional deficiency
Lymphatic insufficiency	Old age
Repetitive trauma	Uremia
Reduced sensation	Glucocorticoid therapy, immunosuppressive agents

The use of systemic laboratory investigations should be limited to specific indications; “routine” blood work is not required for patients with acute or chronic wounds. White blood cell differential counts and blood cultures can confirm the diagnosis of systemic infection. Serum prealbumin may be valuable in determining nutritional status. A greatly elevated erythrocyte sedimentation rate and C-reactive protein can help confirm the diagnosis of osteomyelitis or be used to monitor treatment response. Other

laboratory tests to confirm the diagnosis and severity of associated medical conditions may be justified for specific indications.

Treatment of the Problem Wound

Once a wound has been fully evaluated, the treatments should be designed to address any modifiable causes for the wound and then to achieve specific targeted goals. In order of greatest priority, these goals are: (a) prevention of complications resulting from the wound, (b) preserving or restoring critical functions, (c) achieving wound closure, and (d) restoration of aesthetics.

Preventive Treatment

The preventive measures that should be taken for patients with open wounds depend on the setting. For an acute laceration, tetanus prophylaxis should be considered. For patients with pressure sores, a strict adherence to pressure-relief protocols, optimization of wheelchair seating/bedding, optimization of social support and wound care, and an assessment of nutritional status take priority. In wounds caused by human or animal bites, prophylactic antibiotics are warranted. In addition, any associated medical conditions that are contributing to the wound must be aggressively optimized including glucose control, vascular disease, and contributing medications. It is the responsibility of the surgeon to ensure that a patient with a wound does not develop a complication from that wound and that the patient does not develop more wounds from the same mechanism. This is of particular importance in bedridden, obtunded, or paralyzed patients, in whom it should be possible to completely prevent pressure sores with proper nursing or family care.

Preservation of Function

Preserving joint motion must always be considered for patients with open wounds of the extremities. Aggressive physiotherapy to maintain or improve joint motion can be instituted in the presence of an open wound. Splinting should be used to minimize joint contractures and any plans for wound closure should include measures to maintain joint function. In the case of facial defects, especially if facial paralysis is present, oral competence and the maintenance of eye protection should weigh heavily into any reconstructive plan. Function takes precedence over form in the reconstructive algorithm.

Nonsurgical Therapy

After careful consideration of preventive measures and the preservation of critical function, a strategy for wound closure can be formulated. The basic tenet is: “débride dirty wounds, close clean wounds.” Therefore, the first step in wound closure is achieving control of the wound by eliminating necrotic debris and controlling any infection present. Nonsurgical therapies are used in conjunction with surgical therapy to achieve a clean wound. The mainstay of local, nonsurgical therapy is the use of wound dressings. It is beyond the scope of this chapter to review the wide range of options available to dress wounds. Recent articles contain a contemporary review of this topic.^{6–8} However, the basic principle is to employ débriding dressings for dirty wounds and occlusive dressings for clean wounds. The most commonly employed débriding dressing is the “wet-to-dry” dressing. Gauze made damp with normal saline, weak acetic acid, weak bleach, or various other solutions is applied to the wound. Over a period of hours, evaporation dries the dressing, which becomes slightly adherent to the wound surface. When the dressing is removed, necrotic debris and biofilm is removed with the dressing, but healthy tissue is left behind. Wet-to-dry dressings work through *mechanical débridement*, and the most important component of their use is how often they are changed. Wet-to-dry dressings must be changed a minimum of twice per day, although more frequent dressings may be necessary in certain wounds. These dressings should not be “soaked” off to reduce patient discomfort because this technique completely defeats their purpose. Enzymatic dressings have also been used to débride wounds, but their use can be limited by patient tolerance to the pain they cause. Débriding dressings are indicated for infected wounds and wounds containing necrotic debris.

If a wound is “clean,” meaning that it does not contain necrotic debris and has an acceptable bacterial load, a dressing that maintains a moist wound environment to encourage wound healing should be used.⁸ For many simple wounds, allowing a scab to provide the moist healing environment or the application of a nonadherent sterile dressing is all that is required. In the case of more complex wounds, occlusive dressings that maintain a moist environment to maximize wound healing are preferred. Options include hydrocolloid dressings, alginate dressings, and various hydrogels. Again, occlusive dressings must not be used on infected or dirty wounds. For many wounds, judicious application of hydrocolloid dressings may allow closure by secondary intention in a reasonable period of time.

Under some circumstances, it is appropriate to use antibiotic dressings. Multiple combinations of topical antibiotics are available over the counter and generally cover gram-positive bacteria. Mupirocin ointment has the added benefit for treating methicillin-resistant staph aureus (MRSA) colonization. Burn wounds are most commonly dressed with silver sulfadiazine or mafenide acetate due to their high antimicrobial activity. The low toxicity and excellent antibiotic properties of elemental silver have led to the development and widespread use of wound dressings containing nanocrystalline silver including both barrier dressings and in combination with alginates for daily wound care. In general, however, antibiotic dressings are not required for clean wounds, even if they are chronic.

Finally, it should be noted that we are entering a new era of nonsurgical wound management. A rapid advance in our understanding of wound healing has led to the development of growth factor therapy, cellular therapy, and new physical modalities for the treatment of chronic wounds.⁶ Although recombinant platelet-derived growth factor appears to be a useful adjunct to the dressing regime for pressure sores and diabetic foot ulcers,^{9,10} there is general agreement that exogenously administered growth factors currently play a limited role in the management of acute and chronic wounds.¹¹ Similarly, laboratory data point to the potential for the use of stem cells as a modality to treat difficult wounds, but cellular therapy for clinical wounds is still largely investigational.^{6,12}

There has also been an increase in tissue-engineered dressings and skin substitutes.^{13,14} For example, Integra (Integra Life Sciences Corp., Plainsboro, New Jersey), a bilaminar skin substitute composed of a collagen matrix base with a silicone rubber barrier layer has proven extremely useful in the management of complex wounds and allowing for granulation tissue in compromised wound beds in burns, trauma, and oncologic resections. The development of human, bovine, and ovine acellular dermal matrices are being used in wound care and structural reconstruction of the abdominal wall and breast.¹⁵ The development of new tissue-engineered adjuncts to wound healing remains a very active area of research in plastic surgery.

Negative-pressure wound therapy has become more widespread and can be efficacious and cost effective when applied appropriately for complex wounds.^{16–18} Multiple commercial products exist, but all are similar in the use of a sponge-like material connected to a suction device. There is additional variation in sponge material and inclusion of antimicrobial silver that can be used in specific clinical situations. Extensive experimental and clinical data confirm that the negative-pressure wound therapy promotes tissue perfusion, reduces edema, favorably alters wound fluid composition, and stimulates the formation of granulation tissue.¹⁸ Although these systems are easy to use, decrease the frequency of dressing changes, and can manage edema fluid, their use is contraindicated in acutely infected wounds and requires clinical judgment in balancing the tradeoff between negative-pressure therapy and other wound control methods.

Multiple other modalities, such as hyperbaric oxygen treatment, are in use and are being developed on an ongoing basis, underscoring the high prevalence, the significant cost, and the clinical challenge that are posed by complex wounds. Despite these ongoing developments, the basic algorithm for evaluation and nonsurgical management of wounds will not change.

Surgical Therapy

Wound Preparation. For problem wounds, surgical therapy is primarily aimed at wound preparation and wound reconstruction. For dirty wounds with necrotic debris, a judicious but thorough surgical débridement can convert a contaminated, chronic wound into a fresh surgical wound ready for immediate closure. Although débriding dressings can prepare wounds for closure under some circumstances, an operative débridement is preferred to a long course of débriding dressings for most problem wounds. Consequently, most complex wounds require an operative débridement prior to definitive reconstruction. In the case of chronic osteomyelitis, a formal resection of the sequestrum is required before formal wound closure. Prolonged treatment with intravenous or oral antibiotics cannot clear bacteria from a focus of dead bone; chronic osteomyelitis is a surgical disease cured with a saw, rongeur, bur, or bone curette. Therefore, the common practice of placing patients with chronic osteomyelitis on 6 weeks of antibiotic therapy is irrational unless performed in conjunction with a formal sequestrectomy.

ETIOLOGY

Table 109-3 The Reconstructive Ladder

1. Primary wound closure
2. Healing by secondary intention
3. Skin grafting
4. Local flaps
5. Regional flaps
6. Distant flaps

Reconstructive Principles. As stated earlier, there is no “right” way to close any given wound. Plastic surgeons use a straightforward set of principles in delineating the optimum way to close a given wound for a given patient. The predominant principle is that the simplest method to close a wound is usually the best choice. This principle is embodied in the “reconstructive ladder,” which is a hierarchy of reconstructive options progressing from simple to complex (Table 109-3). Therefore, when engaging options for wound closure, plastic surgeons “climb” the reconstructive ladder, usually stopping on the lowest rung that will achieve a closed wound. However, other principles of reconstruction sometimes override a slavish adherence to the reconstructive ladder. The choice of a technique for wound closure should take into consideration the need for subsequent procedures and other factors that might mitigate skipping over simpler options for wound closure. An example would be an avulsion injury to the palm of the hand. Although it might be possible to close this wound with a skin graft, the need to restore flexor tendon function is preeminent in the hand, so that the use of a distant flap to provide a suitable bed for tendon grafting may be the preferred choice. In addition to the reconstructive ladder, other examples of guiding reconstructive principles are: function takes precedence over form, single-stage reconstructions are preferred over multistage approaches, and autologous tissue is preferred over alloplastic reconstructions. Other factors to be considered are the durability of the reconstruction over many years, the psychological impact on the patient, and data indicating that some options are sometimes preferred for specific reasons. For any reconstruction, the surgeon must carefully consider the potential secondary consequences of the reconstructive technique and morbidity at the donor site. The increased identification of alternative flap donor sites with less morbidity reconstruction has changed the reconstructive paradigm to sometimes use a “reconstructive elevator” to higher-level reconstructions to better address the secondary reconstructive outcomes. Thus, weighing this complex array of factors to arrive at the optimal reconstruction for a given patient is the true challenge in reconstructive surgery.

Reconstructive Techniques. Regardless of the reconstructive method chosen, plastic surgeons strive for technical virtuosity in the operating room. To maximize healing and minimize scar formation, atraumatic technique includes delicate tissue handling, the use of skin hooks and sharp rakes, bipolar electrocautery, sharp dissection, and loupe magnification. When reconstructing difficult wounds, the margin for error is minimal, and small errors in technical execution can result in failure. It is also critical that secondary plans for reconstruction are considered and preserved during an initial reconstructive attempt. The general surgical methods used by reconstructive surgeons are briefly considered in this chapter.

An important distinction is made between a graft and a flap. A graft consists of tissue that is transferred into a defect in a devascularized state and requires a vascularized environment and subsequent vascular ingrowth in order for incorporation. Skin, fat, muscle, tendon, fascia, cartilage, and bone can all be used as grafts; however, the volume of each that can be successfully incorporated depends on the surrounding wound environment and the physiologic principles of each tissue. In contrast, flaps consist of tissue that is transferred while remaining vascularized. Flaps are much less dependent on the local environment for survival given the inherent blood supply and can be used when immediate coverage is necessary or when the underlying defect will not support a graft. Free tissue transfer (or a “free flap”) is the transfer of tissue on a single vascular pedicle which is immediately anastomosed at the recipient site allowing for the transfer of vascularized tissue from a separate area of the body.

Primary Closure. If a laceration or other wound can be closed primarily, consideration is given to a meticulous, layered closure. Emphasis is placed on eversion of skin edges without strangling tissue. Nonabsorbable skin stitches that provoke minimal inflammatory response are preferred, but they must be removed promptly to minimize cross-hatching. Therefore, for most wounds, deep dermal, absorbable stitches are placed to allow early removal of skin stitches while still providing prolonged support to the repair; this may minimize the chances of a dehiscence or scar spread. It is preferable to place a closed suction drain to eliminate dead space rather than suturing fat or other easily devascularized tissue. If a

technically perfect repair under physiologic tension cannot be achieved with primary closure, it is preferable to use a more complex surgical option.

Skin Grafting. Skin grafting was one of the foundations on which the specialty of plastic surgery was established. Skin grafts are classified as either split thickness, where epidermis and a portion of the dermis are harvested, or full thickness, where the epidermis and the entire dermis are harvested. Both full-thickness and split-thickness skin grafts can be used to resurface open wounds in cases in which primary closure is not possible. Skin graft take is contingent on the successful revascularization of the graft within a narrow time window (48 to 72 hours). Initially, grafts are nourished by a process of plasmatic imbibition, wherein serum from the wound bed diffuses into the adjacent graft. Revascularization occurs by the process of inosculation and angiogenesis. Vessels from the wound bed grow into the graft, forming functional circulatory connections with the vasculature of the graft. For plasmatic imbibition and inosculation to be successful, two criteria must be met. First, the wound bed must be appropriately vascularized. Therefore, skin grafts cannot be placed on poorly vascularized wound surfaces, including bone denuded of periosteum, tendon denuded of peritenon, or cartilage. Second, a bolster dressing or splint must be used to ensure absolute immobilization of the graft on the bed to prevent shearing of the nascent vascular connections during inosculation. If either of these criteria cannot be met, a more complex reconstructive option must be considered. Split-thickness graft donor sites heal due to epithelial cell growth from the base of remaining hair follicles and skin appendages. A full-thickness graft donor site must either be closed primarily or reconstructed with a different technique.

Random Skin Flaps. The use of tissue (usually skin) immediately adjacent to the defect as the tissue for reconstruction is referred to as a local flap reconstruction. Skin rearrangement can range in complexity from simple undermining to complex, geometric skin flaps. Which method is appropriate is dependent on multiple factors, including the etiology of the defect, the desired direction of the scar, the fragility or mobility of underlying structures, and the need to avoid distortion to adjacent free margins such as the lip or eyelid. Significant experience is required for the optimal utilization of skin rearrangement. When plastic surgeons think of “classical” skin flaps, they are referring to random skin flaps, without an axial blood supply. These skin flaps rely on a dermal plexus of vessels for their survival, and the perfusion of the distal end of the flap is inadequate to allow tissue survival if the flap design is inappropriate. It was previously thought that survival of the distal part of random skin flaps could be ensured by adhering to length-to-width ratios established for various areas of the body. It is now recognized that these ratios have no basis in circulatory physiology, and the surviving length of a random skin flap does not depend on flap width.¹⁹ In practice, most of the commonly employed skin flaps have been developed empirically. There are three basic types of random skin flaps: rotation, advancement, and transposition, depending on how adjacent skin is shifted into the defect. Each type of flap has specific design criteria and choice of flap design is based on wound location, patient anatomy, and surgeon preferences. Excellent reviews of the use of skin flaps in reconstructive surgery are available.^{20,21}

As mentioned, the concern with flap viability limits the utility of random skin flaps. Several strategies have been developed to circumvent this problem. The first of these is the concept of surgical delay. Delay is defined as the partial interruption of blood flow to a defined piece of tissue allowing for preconditioning of the tissue prior to further division or transfer. At present, surgical delay is the only method available to augment the surviving length of random skin flaps ([Fig. 109-1](#)). Another strategy is the use of tissue expanders. Tissue expanders are implantable balloons that are inserted in a deflated state and are inflated with sterile saline via percutaneous injection into a self-sealing valve. Except for the scalp, where expanders are placed in the subgaleal plane, tissue expanders are usually placed subcutaneously. In fact, the insertion of the tissue expander into a subcutaneous pocket creates a surgical delay, and the slow expansion has been demonstrated to result in the formation of new skin. However, the most important strategy to circumvent the use of random skin flaps has been to develop axial pattern flaps that do not rely on a random blood supply.

Figure 109-1. Example of surgical delay. Because of associated medical problems, the patient was not a candidate for microvascular tissue transfer. **A:** Lower-third tibial defect secondary to an open ankle fracture. Note exposed bone, which precludes use of a skin graft. **B:** In the first stage, a bipedicle flap was created anterior to the defect. The deep perforators to the skin of the flap were divided by full undermining. The flap is perfused only from the proximal and distal ends. **C:** The incisions were repaired, and the wound was dressed. **D:** After 5 days, the bipedicle flap was again elevated and part of the distal pedicle was divided (*arrow*). The incisions were again closed, and the wound was dressed. This procedure was repeated 10 days after the initial operation to leave only a small skin bridge at the distal end of the flap. **E:** Fourteen days after the initial procedure, the remaining distal skin bridge was divided and the flap transferred. The donor site was skin grafted. This photograph depicts full survival of the flap and complete take of the skin graft.

Flaps with Axial Blood Supply. Regional flaps are defined as the transfer of tissue that is not immediately adjacent to the defect without the disruption of blood supply to the transferred tissue. For this approach to be practical, an axial blood supply to the transferred tissue must be present.

Axial Skin Flaps. The pioneering work of Bakamjian²² and McGregor and Jackson²³ identified longitudinal blood vessels of large caliber traversing a defined region of skin. Their descriptions of the deltopectoral and groin flaps, respectively, opened a new era of reconstructive surgery. Surgeons were no longer constrained to the use of random skin flaps; any piece of tissue in the body with an axial blood supply could be transposed on a vascular pedicle with a high degree of assurance that the tissue would survive. Taylor and Palmer's²⁴ description of the angiosome concept solidified our ability to design flaps based on a sound knowledge of vascular anatomy. An angiosome is defined as a region of tissue supplied by an identifiable, and usually named, artery and its venae comitantes. Because of the ability of choke vessels crossing angiosome boundaries to enlarge, flaps can be designed to encompass an adjacent angiosome. In practice, there are relatively few axial skin flaps, most being better classified as fasciocutaneous flaps.

Fasciocutaneous Flaps. Cormack and Lamberty²⁵ further expanded our understanding of the blood supply to the skin with their description of fasciocutaneous flaps. They pointed out that the dermal plexus derives its inflow from vertically oriented vessels arising at the level of the deep fascia. The vessels at the deep facial level have horizontal orientation relative to the skin’s surface and form a subfacial plexus. This subfacial plexus can form the basis for the design of fasciocutaneous flaps based on several defined anatomical patterns.²⁵ Several fasciocutaneous flaps have enjoyed widespread use. The radial forearm flap has become a workhorse for hand reconstruction and as a free flap for head and neck reconstruction. The anterolateral thigh (ALT) flap has become a common flap for larger reconstructive needs and is based on septal or muscular perforators from the descending branch of the lateral femoral circumflex artery. The osteoseptocutaneous fibula free flap has been widely used for intraoral reconstruction during reconstruction of oromandibular defects and a primary site for vascularized bone flap harvest.

Muscle and Myocutaneous Flaps. Based on the knowledge that tissue with an axial blood supply can be reliably transferred, muscle and myocutaneous flaps came into widespread use in the 1980s, thanks in large part to the classification system by Mathes and Nahai.²⁶ Whole muscles can be transferred as a pedicled or free flap if a dominant vascular pedicle is present. Segmental muscle transfers are sometimes possible on minor vascular pedicles. Functional muscle transfer can also occur when innervation is preserved or the motor nerve is coapted to a different motor nerve.

The rediscovery of the musculocutaneous perforator as a predominant vascular supply to the skin in many areas of the body has led to the wide use of musculocutaneous flaps. These flaps derive their inflow from a major muscular artery used to also bring skin along with the underlying muscle. Perforators emanating vertically from the muscle surface supply the skin overlying the muscle. [Table 109-4](#) lists “workhorse” muscle and myocutaneous flaps. Of particular note is the transverse rectus abdominis myocutaneous (TRAM) flap, based on periumbilical myocutaneous perforators from the rectus abdominis muscle has been widely employed for breast reconstruction.²⁷ An extension of this concept has led to the increasing use of “perforator” flaps. Perforator flaps are based on fasciocutaneous or myocutaneous perforating vessels. Dissection isolates the skin and subcutaneous tissue to be transferred on one or more perforating vessels; the underlying muscle is left intact, eliminating the functional disturbance that would result if a whole muscle was harvested. Because of their robust vascularity and ability to minimize donor deficit, perforator flaps are often preferred in reconstructions where muscle is not necessary and preservation of the underlying muscle decreases the morbidity at the donor site. An example is highlighted in the section on breast reconstruction where the use of the deep inferior epigastric perforator (DIEP) flap is based on the same donor site anatomy as a TRAM flap, but preserves the rectus abdominis muscle. In reconstructive surgery a large number of perforator flaps have been described and are now used as both pedicled and free flaps.²⁸

CLASSIFICATION

Table 109-4 Workhorse Muscle, Myocutaneous, and Perforator Flaps

Flap	Myocutaneous	Perforator	Common Uses
Temporalis	No	No	Orbital and intraoral reconstruction, facial reanimation (pedicled flap)
Pectoralis major	Yes	No	Intraoral and neck reconstruction; reconstruction of sternal defects (muscle only)
Latissimus dorsi	Yes	Yes	Breast reconstruction, neck reconstruction, free flap for very large defects
Rectus abdominis	Yes, including TRAM	Yes, including DIEP	Breast reconstruction, sternal reconstruction, reconstruction of groin defects, free flap for medium-sized defects
Gluteus maximus	Yes	Yes, including SGAP	Ischial pressure sores, sacral pressure sores, SGAP used for breast reconstruction
Biceps femoris	Yes	No	Ischial pressure sores
Tensor fascia lata	Yes	No	Trochanteric pressure sores, abdominal wall reconstruction
Gracilis	Yes	Yes	Perineal reconstruction, vaginal reconstruction, facial reanimation (muscle free flap), free flap for small defects
Rectus femoris	Yes	No	Infected hip wounds, abdominal wall reconstruction
Medial gastrocnemius	Rarely	No	Knee defects, proximal third tibial defects
Soleus	No	No	Middle third tibial defects

DIEP, deep inferior epigastric perforator; SGAP, superior gluteal artery perforator; TRAM, transverse rectus abdominis myocutaneous.

Microvascular Tissue Transfer. Historically, pedicled flaps were used to reconstruct distant defects. The distant transfer was accomplished in one of two ways. Flaps could be moved to the defect in a series of pedicled transfers (waltzing or tumbling flaps). Alternatively, flaps could be attached directly to the defect with a temporary pedicle to the donor site being maintained temporarily. At a second stage the flap was detached from the donor site, after it had developed sufficient blood supply from the recipient bed (e.g., cross leg flaps, pedicled groin flaps). Although the distant transfer of pedicled flaps still has definitive indications (e.g., the median forehead flap for nasal reconstruction), reconstruction using distant tissue is now most commonly performed via microvascular tissue transfer, or “free” flaps. First described clinically by Daniel and Taylor,²⁹ free flaps have revolutionized reconstructive surgery. Any tissue with an axial blood supply with pedicle vessels 1 mm in diameter or larger can be reliably transferred microsurgically and improved techniques have opened the door to supermicrosurgery and the anastomosis of vessels between 0.3 and 0.8 mm in diameter.³⁰ Circulation in the transferred tissue is established via microvascular anastomoses between the axial flap vessels and vessels in the recipient site. Microvascular anastomoses are performed with 8-0 or 9-0 suture with the aid of an operating microscope; success rates for free flap transfers exceed 95%.³¹ The greatest advantage of free flap reconstruction is that the surgeon is not restricted to the use of available, local tissues; any flap or composite block of tissue that has feeding vessels large enough for microvascular anastomoses can be transferred with this technique. By using composite tissue flaps, massive, complex tissue defects can be reconstructed replacing “like with like” (Fig. 109-2).³² The transfer of tissue to the site of reconstruction from another area of the body allows the use of tissue which has not been exposed to the damaging effects of radiation or scarring. Bowel, skin, bone, muscle, fascia, and composite tissue can be transferred microsurgically with new flaps continuing to be described clinically. Free flaps are the primary modality for reconstruction of major head and neck defects after composite resection and for the reconstruction of traumatic defects in the distal foreleg. As already mentioned, perforator flaps are increasingly used as microsurgical tissue transfers. The anterior lateral thigh (ALT) perforator flap has become a workhorse for reconstruction of a diverse array of complex defects, especially after extirpative surgery of the head and neck. The deep inferior epigastric artery perforator (DIEP) flap rivals the TRAM as the mainstay for autologous breast reconstruction.³³

The future of reconstructive techniques continues to evolve. The use of prelaminated and prefabricated flaps can now be used to create complex reconstructions elsewhere on the body and then transfer that reconstruction en bloc to the recipient site.³⁴ Tissue-engineered reconstructions are emerging with the modification of both biologic and nonbiologic tissues including the modification of stem cells, generation and cellularization of scaffolds, and three-dimensional (3D) printing for reconstructive purposes.³⁵ In addition, vascularized composite allotransplantation (VCA) has now been successfully performed in multiple areas including both hand and facial transplantation.³⁶ Continued work on immunosuppression modification should continue to shift the risk–benefit ratio toward standard reconstructive techniques.

RECONSTRUCTIVE AND AESTHETIC SURGERY OF THE BREAST

Plastic surgery of the female breast includes both reconstructive and aesthetic procedures. Breast reconstruction following mastectomy and reduction mammoplasty for macromastia (oversized breasts) are the most common examples of reconstructive breast surgery. By contrast, breast augmentation (enlargement) and mastopexy (breast lift) generally are performed for aesthetic reasons. Although some surgical approaches may be applicable to both categories of breast procedures, the relative benefits, risks, and costs of reconstructive versus aesthetic breast surgery may be quite different, particularly as viewed by patients, providers, and payers.

Before advising women on reconstructive or aesthetic breast procedures, the surgeon should carefully assess the patient's current preferences, concerns, history, and physical findings. Initially, any history of breast disease (as well as familial history of breast pathologies) should be evaluated. On physical examination, careful linear measurements and preoperative photographs should be taken to document existing contour deformities, asymmetries, or other findings. A standard breast examination should be carried out to detect previously undiagnosed masses, nipple discharge, or lymphadenopathy. Finally, it is also advisable that women age 40 years or older undergo mammography unless this study has been performed in the previous 12 months.

Preoperative consultation should include a thorough discussion covering the relative benefits and risks of the various surgical options. The surgeon is well advised to provide comprehensive information in an understandable format. To enhance patient satisfaction with the eventual surgical result, providers should elicit patients' preferences and expectations for surgical outcomes and tailor treatment options accordingly. Because of the prevalence of breast cancer in North American women, the impact of reconstructive or aesthetic procedures on breast cancer monitoring also should be discussed.

Reconstructive Breast Surgery

Postmastectomy Reconstruction

1 A variety of operative procedures have been described for breast reconstruction following mastectomy. These approaches can be categorized as implant-based, autogenous (natural) tissue, and "hybrid" procedures. For purposes of this discussion, the term *hybrid* is applied to procedures combining elements of both implant and autogenous tissue techniques. This overview describes the advantages and disadvantages of the most common techniques. Ultimately, procedure selection is based on a range of patient variables, including size and shape of the desired reconstructed breast; availability of local, regional, and distant donor tissues; coexisting medical problems; and, perhaps most important, patient preferences.

Implant-Based Techniques. As most commonly practiced, implant-based breast reconstruction is either performed as a staged tissue expander–implant reconstruction or as a "single stage" implant reconstruction. The tissue expander–implant approach usually requires two or more operative procedures to reconstruct the female breast. In the first stage, a temporary tissue expander is placed in a soft tissue pocket, usually located deep to the pectoralis major muscle. The tissue expander is a deflated silastic (silicone) envelope with an integrated or remote injection port through which saline solution can be percutaneously injected. Expanders can be completely covered with a combination of flaps including the pectoralis major (superior), serratus anterior (lateral), and rectus fascia (inferior). Alternatively, with the introduction of acellular dermal matrices (ADMs), expanders are now routinely covered with a pectoralis major muscle flap superiorly and ADM sling inferiorly. Following expander placement and meticulous closure of the overlying muscle and skin, saline is periodically injected beginning at 10 to 21 days. As the device enlarges, growth is induced in the overlying skin, recreating soft tissue coverage for the new breast.³⁷

Figure 109-2. Double free-flap reconstruction of a massive, complex defect. **A:** Squamous cell carcinoma of lip, chin, mandible, and floor of mouth after resection. Massive tissue defect encompasses skin of the chin, entire lower lip, mandible from midbody to midbody, and floor of the mouth. **B:** Fibula free flap. Skin paddle is centered on fasciocutaneous perforators. **C:** Fibula free flap elevated but still in situ. Osteotomies have been performed to conform to the mandibular contour. The skin paddle will form the floor of the mouth. **D:** Radial forearm free-flap plan. Skin paddle will be harvested along with the palmaris longus tendon. The tendon will be attached to the modiolus on either side of the lower-lip defect, and the skin paddle will reconstruct the skin of the chin and lip. For the lip, the skin paddle will be draped over the tendon like a bed sheet on a clothesline. **E:** Radial forearm flap elevated but in situ. **F:** Postoperative result, mouth closed. **G:** Postoperative result, mouth open. (Reproduced with permission from

Following completion of expansion, most surgeons delay the second stage of reconstruction for 1 to 4 months to allow for maximal skin growth. At the conclusion of this hiatus, the second procedure is performed, consisting of removal of the expander and placement of the reconstructive implant. Currently available breast implants include a range of options, including variations in shape (round vs. “anatomic” or teardrop configurations), fill material (silicone gel vs. saline), and surface configuration (smooth vs. textured envelopes). The relative advantages and disadvantages of these options are discussed in the Breast Augmentation section later in this chapter. As the most common option for postmastectomy reconstruction in the United States, the expander–implant approach offers several advantages. The lengths of the surgical procedures associated with this approach usually are relatively brief (often 1 hour or less) and are technically straightforward. Particularly when employed in bilateral reconstruction cases, resulting symmetry and aesthetic outcomes are relatively good (Fig. 109-3).

Patients considering implant reconstruction should also be mindful of the disadvantages of these procedures. The expander–implant approach usually requires at least two surgical procedures, multiple visits for expansion, and approximately 6 to 12 months to complete. For patients eager to return to a normal lifestyle following breast cancer treatment, this delay can be particularly frustrating. In addition, tissue expanders and reconstructive implants have been associated with a number of complications. Early in the postoperative period, these devices may be troubled by delays in wound healing, at times resulting in implant exposure and requiring explantation. Implant infections also may necessitate removal of the prosthetic device. Late complications include expander or implant leakage. Also, the development of excessive scar tissue surrounding the implant (termed a *capsular contracture*) can produce a hard, painful, or deformed breast requiring surgical revision.

Figure 109-3. Staged bilateral tissue-expander based breast reconstruction. A, B: Pre-operative appearance. C, D: After tissue expansion. E, F: Final result after expande/implant exchange and nipple-areolar complex tattooing.

Figure 109-4. Transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.

The “single stage” approach to implant reconstruction bypasses the tissue expander stage, with immediate placement of a full-sized silicone or saline-filled implant.³⁸ Similar to the tissue expander–implant reconstruction, patients will need revision procedures to achieve a complete reconstruction. The use of ADMs have made this option of reconstruction possible as larger volumes can be placed under an ADM; complete coverage with muscle limits the intraoperative volume placed in an expander at the initial reconstruction. Careful patient selection is necessary when considering this option and patients need to understand the reconstructed breast volume will be about the same size or smaller than their premastectomy volume. Patients who desire to be larger are better served with tissue expansion.

2 Autogenous Tissue Reconstruction. A variety of autogenous (natural) tissue options have been

described for postmastectomy breast reconstruction. Currently, the most commonly performed of these procedures are based on the lower abdominal soft tissue. Originally popularized by Hartrampf et al.³⁰ the TRAM (transverse rectus abdominis myocutaneous) flap was the earliest lower abdominal flap routinely used for breast reconstruction. The flap was commonly performed as a pedicle muscle flap, with transfer of the rectus muscle which is left partially attached to the costal margin, preserving the superior epigastric artery and vein as the flap's blood supply (Fig. 109-4A and B). These tissues are tunneled subcutaneously into the mastectomy defect, where they are sculpted into the desired breast size and shape. Meanwhile, the abdominal donor site is closed by reapproximating the anterior rectus sheath and by advancing the remaining superior skin edge of the donor site as a modified abdominoplasty (Fig. 109-4C). As harvest of the pedicled TRAM flap requires use of an entire rectus muscle and a segment of the abdominal wall fascia, occurrences of postoperative abdominal hernias or (more commonly) abdominal wall laxity are a persistent problem, particularly in patients who undergo bilateral reconstruction using this technique.³⁹

Microsurgical techniques for soft tissue transfer have allowed for modifications of the TRAM flap and have also encouraged the development of other alternative flap options. Other lower abdominal flap options requiring microsurgical free-tissue transfer include the free TRAM, muscle sparing TRAM, DIEP (deep inferior epigastric perforator) and SIEA (superficial inferior epigastric artery) flaps. Differences between these flap techniques are based on the amount of rectus muscle and fascia harvested with the flap, with the DIEP and SIEA flaps avoiding muscle or fascia harvest. Allen and Treece took the free TRAM flap a step further with their development of the DIEP flap: by meticulously dissecting vascular perforators from the deep inferior epigastric pedicle into the overlying abdominal fat, avoiding removal of any rectus abdominis muscle or fascia (Fig. 109-5A and B), thereby minimizing disruption of abdominal wall structures.⁴⁰ This consequently decreases the occurrence of abdominal bulges or hernias.^{39,41,42} The flap is transferred to the chest where the flap vascular pedicle is anastomosed to recipient vessels in the chest with the aid of an operating microscope or high-power surgical loupes. The more common recipients utilized today are the internal mammary vessels (Fig. 109-5C), with the thoracodorsal vessels serving as a second option.

Abdominal soft tissue flap breast reconstruction offers several benefits. Because the flaps usually provide a generous amount of lower abdominal adipose tissue for breast bulk, implants are rarely needed with this approach (Figs. 109-6 and 109-7). The flaps can be inset and sculpted in a virtually infinite number of ways, giving the reconstructive surgeon considerable latitude in the creation of breast shapes and sizes. An additional advantage of abdominal-based flaps is their tendency to gain or lose volume in association with weight changes and body mass, thereby maintaining better symmetry than implant reconstructions over time. Finally, flap reconstructions avoid long-term problems encountered with implants such as implant rupture, which may necessitate additional surgical procedures. Likely based on these benefits, patients tend to be more satisfied with soft tissue flap breast reconstruction than implants in the long term.⁴³ Despite these advantages, lower abdominal flaps also are associated with some disadvantages. Compared with implant approaches, flap reconstruction requires an abdominal scar, longer operations, hospitalizations, and recovery times. Furthermore, flap procedures can produce a range of complications, including partial and total flap loss as a result of vascular compromise of the transferred tissue.

Figure 109-5. Deep inferior epigastric artery perforator (DIEP) flap. **A:** abdominal donor site. **B:** Flap harvested without muscle or fascia. **C:** Microvascular anastomosis to internal mammary vessels.

Figure 109-6. DIEP breast reconstruction. A, B: s/p left mastectomy. C, D: After left DIEP flap reconstruction. E, F: Final result after tattooing of nipple-areolar complex.

The free flap concept also has been applied to other donor sites for breast reconstruction, most notably the thighs (transverse upper gracilis and profunda artery perforator flaps) and gluteal region (superior and inferior gluteal artery perforator flaps).⁴⁴⁻⁴⁷ Although perforator flaps appear to avoid the functional deficits associated with muscle flap harvest, they (like all free tissue transfers) entail longer, technically challenging operations requiring special facilities, equipment, and expertise. Also, because the blood supply for the entire flap depends on two or three microsurgical anastomoses (each usually involving vessels no more than 2 to 3 mm in diameter), there is the potential for complete flap loss in the event of anastomotic thrombosis. Flap loss rates are however relatively low at 1% to 2% in high-volume centers.

“Hybrid” Breast Reconstruction Techniques. As an additional alternative for breast reconstruction, flaps can be used in concert with saline or silicone-gel implants. Most commonly, the ipsilateral latissimus dorsi and a segment of overlying skin are harvested as a musculocutaneous pedicle flap and are tunneled anteriorly into the mastectomy defect. Although the latissimus dorsi and its associated skin island constitute an extremely reliable flap when used for wound coverage, this approach usually provides insufficient bulk for breast volume. Tissue expanders or implants are often used to address this volume deficiency. The combination of a latissimus dorsi flap and tissue expansion may be particularly appropriate for cases in which the remaining mastectomy skin is of insufficient quality or quantity to tolerate tissue expansion. Following transfer and expansion of a latissimus dorsi musculocutaneous flap, an appropriately sized breast implant usually can be safely placed in a secondary operation.

Nipple–Areolar Reconstruction. Reconstruction of the nipple–areolar complex (NAC) can be accomplished at the conclusion of breast mound reconstruction or at a later date. Following recreation of the mound, many surgeons prefer to allow several months for tissue healing and settling before proceeding with nipple–areolar reconstruction. To recreate the papule, common options usually rely on local skin flaps or a segment of redundant contralateral papule. For the areola, a full-thickness skin graft or tattooing of the surrounding skin can be used. In recent years 3D tattooing of the NAC has been introduced as an alternative to surgical reconstruction with good aesthetic results ([Fig. 109-8](#)).⁴⁸

Breast Reduction (Reduction Mammoplasty)

Because reduction mammoplasty is intended to alleviate functional problems and symptoms of macromastia, this procedure is considered a reconstructive rather than an aesthetic operation. In general, appropriate candidates for reduction mammoplasty are women with macromastia and associated back, neck, or shoulder pain; limitations in daily work or recreational activities; or difficulties obtaining proper fit in bras or other clothing. Although reduction mammoplasty usually is a covered benefit by most health care payers, patients symptomatic and functional concerns must be carefully assessed and documented before proceeding with surgery. As noted earlier in this section, patients preferences and expectations regarding postoperative breast size, shape, and functional results also should be carefully evaluated.

Figure 109-7. DIEP breast reconstruction. A: Pre-operative appearance. B: Post-operative, showing abdominal donor site scars.

Figure 109-8. A: Standard nipple-areolar complex tattooing after nipple reconstruction. B: 3D tattooing of nipple-areolar complex without nipple reconstruction.

Although a variety of approaches have been described for breast reduction, common surgical options share a number of characteristics. Most techniques of breast reduction resect both breast parenchyma and redundant skin. Also, reduction procedures generally reposition the NAC to a more superior point on the breast mound. To maintain nipple viability and sensation, the NAC usually is mobilized as part of a pedicle of breast parenchyma or dermis. Following dissection of the nipple pedicle and reduction of the surrounding breast skin and parenchyma, the pedicle is transferred superiorly with its vascular and neural supplies intact, while the remaining breast is reapproximated around the nipple pedicle.

In categorizing reduction mammoplasty techniques, surgical options often are described in terms of the nipple pedicle design. For example, the most common approaches rely on an inferiorly or centrally based dermal–parenchymal pedicle to maintain vascular and nerve supplies to the NAC (Figs. 109-9A to C and 109-10A to C).^{49–51} In designing skin incisions, traditional methods of reduction often have incorporated a modification of a pattern originally described by Wise.⁵² While allowing considerable flexibility in resection of redundant breast skin, the modified Wise pattern produces an inverted T – shaped scar, the inferior portion of which runs along the inframammary fold (IMF) (Fig. 109-11). In an effort to eliminate the IMF scar, Lejour et al.^{53,54} have described a vertical scar reduction mammoplasty.

Prospective outcome analysis of women undergoing reduction mammoplasty indicate that this surgical intervention produces considerable improvements in somatic pain and in functional status.^{55,56} However, patients and providers also should be aware of the potential risks associated with reduction. Complications reported with these procedures include instances of nipple or skin loss, changes in levels of nipple sensation, hypertrophic scarring or keloid formation, contour deformities, and breast asymmetry.

Aesthetic Breast Surgery

Breast Augmentation (Augmentation Mammoplasty)

Augmentation or breast enlargement is one of the most commonly performed aesthetic procedures. Evaluation of patients seeking breast augmentation should follow the guidelines described earlier. Particular attention should be focused on thoroughly assessing several factors, including patient preferences for postoperative breast size and shape, history of breast disease, and physical findings. The

preoperative examination should evaluate and document any possible breast masses as well as existing breast size, asymmetries, and contour deficits.

In planning augmentation mammoplasty, a variety of approaches and options are available. Decisions regarding these choices are often best reached in consultation with the patient. Implants can be placed through a variety of incisions including periareolar, IMF, and transaxillary approaches (Fig. 109-12). With the advent of endoscopic techniques in recent years, transaxillary augmentation now can be carried out with direct visualization of the implant pocket. This latter approach commonly produces excellent aesthetic results with minimal visible skin scarring.

Location of the implant pocket is another critical decision in augmentation mammoplasty. Implants can be placed anterior to the pectoralis major muscle (“subglandular” location) or posterior to the muscle (“subpectoral” location). Subglandular placement usually results in less postoperative pain, but a submuscular implant location may produce lower rates of capsular contracture⁵⁷ and may pose fewer difficulties in obtaining subsequent mammograms.⁵⁸

Several choices also exist in selection of implant types. Since the mid-1990s, many surgeons have been relying on the use of implants with textured surfaces to reduce capsular contracture rates. Although textured surfaces appear to lessen scar tissue contracture,⁵⁹ some patients and surgeons assert that, compared with the smooth-walled envelope, the thicker, less pliable textured envelope gives the augmented breast a less natural appearance and feel. With the reintroduction of silicone gel-filled implants in the United States, patients and providers also have a choice of implant fill materials. Although gel implants may produce aesthetically superior results compared with saline implants in some patients, diagnosis and surgical treatment of implant rupture may be more challenging with gel devices. Further refinements in silicone gel materials have led to the recent introduction of highly cohesive gel implants which have an anatomic shape and a reduced the risk for gel leakage in the event of rupture. Indications for highly cohesive gel implant use and critical aspects of patient selection are currently under investigation.

Figure 109-12. Breast augmentation via inferior mammary fold (IMF) incisions. **A:** Pre-operative. **B:** Post-operative.

Figure 109-13. **A:** Mild ptosis. **B:** Moderate ptosis. **C:** Severe ptosis.

Whatever options are chosen for breast augmentation, surgeons should clearly communicate with patients about the potential risks of these procedures. The most commonly reported complications include implant rupture, capsular contracture, implant infection, contour deformities, and breast asymmetries.⁶⁰ Despite the potential for local complications, there currently is no substantial evidence that silicone gel filler material or implant envelopes are associated with increased risk for systemic disease. To date, concerns voiced in the early 1990s about adverse “health effects” of silicone breast implants appear to be unfounded.⁶¹ However, over the past decade a few cases of anaplastic large cell lymphoma (ALCL) in patients with breast implants have been reported with growing evidence of an association.^{62–64} The form of ALCL found in patients with implants tends to be benign, often regressing after implant and capsule removal without systemic therapy.^{63,64}

Mastopexy

Mastopexy (or “breast lift”) describes a category of surgical procedures designed to address redundancy or laxity of the breast’s skin envelope, a condition termed *ptosis of the breast*. Breast ptosis can be classified as mild, moderate, or severe, depending on the location of the NAC relative to the IMF (Fig. 109-13). Ptosis occurs when an imbalance exists between the volume of breast parenchyma and the quantity of overlying skin. Mastopexy procedures usually reduce ptosis by removing redundant breast skin and by relocating the NAC to a more superior position. These goals can be achieved through a variety of skin incisions and excisions, many of which closely resemble techniques described earlier for reduction mammoplasty. Fundamentally, mastopexy differs from breast reduction in that mastopexy removes redundant skin while leaving most or all of the breast parenchyma. Approaches to mastopexy range from minimal periareolar techniques to more extensive skin resections using more extensive vertical incisions (Fig. 109-14A and B). As always, patients considering this procedure must weigh the potential benefits of mastopexy (most notably, diminished ptosis) with the disadvantages (scars and risks of complications) associated with the operation. Although relatively rare, the potential complications of mastopexy closely parallel those described for reduction mammoplasty.

RECONSTRUCTIVE SURGERY OF THE HAND

Advances in plastic surgery have improved our ability to reconstruct hands that have been mutilated by trauma, destroyed by arthritic diseases, or impaired by congenital conditions. Innovations in microvascular techniques, wound management, and rigid fracture fixation have expanded the capabilities of plastic surgeons by allowing them to borrow tissues from other parts of the body and use them to reconstruct complex defects in the upper extremity in a single procedure. These innovations provide limitless technical possibilities for the restoration of hand function and the eventual return of patients as productive members of society. The following sections highlight the technical aspects of

hand reconstruction and discuss indications for and applications of these techniques.

Trauma

Replantation

3 Since the first successful finger replantation by Komatsu and Tamai⁶⁵ in 1968, replantation surgery has flourished throughout the world. Thirty years of experience with replantation surgery has improved our understanding of this procedure and has resulted in the development of indication guidelines to ensure that replanted upper extremity parts not only survive, but have acceptable function as well. The absolute indications for replantation (i.e., situations in which replantation should always be attempted) are (a) thumb amputation, (b) multiple finger amputations, (c) pediatric population amputations, and (d) mid-hand, wrist, or distal forearm amputations. The absolute contraindications for replantation are (a) associated life-threatening injuries, (b) multiple-level injury in the amputated part, causing injuries along the vessels and preventing blood flow into the replanted part, and (c) severe contamination of the part, which carries a high probability of systemic infection if replanted. There are other situations in which the benefit of replantation is debatable because outcome data are not available. For example, single-finger amputation at zone II (a tight fibroosseous tunnel extending from the insertion of the superficialis tendon at the middle phalange to the first annular pulley) is generally not recommended. Tendon adhesion after zone II replantation may result in a stiff finger, which can interfere with the overall performance of the hand. On the other hand, single-finger amputation at zone I (distal to the superficialis insertion) is often recommended (Fig. 109-15). A stiff distal interphalangeal joint generally does not cause much impairment, and nerve regeneration to the replanted part is quite rapid because of the short distance to the terminal sensory organs. Furthermore, the aesthetic appearance of zone I replantation is far superior to that of an amputation stump. In the future, the use of patient-related outcome instruments and an increased body of replantation experience among centers will help to define the utility of various digit replantation procedures.

Figure 109-14. Mastopexy procedures. A: Circumareolar technique. B: Vertical scar technique.

Figure 109-15. A: Amputation of the index finger at zone 1 in a mechanic. The patient requested replantation because his work requires fine manipulative tasks. B: Successful replantation with good aesthetic outcome and function.

Toe Transfer

When finger replantation is not possible or not successful, patients are left with significant functional loss. Disability is most severe when the thumb has been amputated at or proximal to the metacarpophalangeal joint or when all of the fingers have been amputated in machine injuries. In these cases, toe transfer to the hand is an effective procedure in restoring grasp and pinch function. Although a prosthesis is available to mimic the thumb, lack of sensation is a major drawback and often leads to disuse of the prosthesis. For a patient who has had a thumb amputation at or proximal to the metacarpophalangeal joint, big toe or second toe transfer to the thumb can create a sensate digit that will oppose to the other fingers. Big toe transfer is advantageous because it provides a broad contact surface and closely resembles the shape of the thumb, particularly when the big toe is trimmed and sculptured to match the size of the thumb. However, the disadvantage of the big toe transfer is the conspicuous donor site appearance in the foot and potential gait problems with foot push-off if the head of the first metatarsal is taken along with the big toe. For these reasons, the second toe has become the preferred method of transfer in some centers (Fig. 109-16). The disadvantage of the second toe transfer procedure is the slender appearance of the digit as compared to the original thumb, but the donor site appearance is quite acceptable. A recent outcome study, using objective physical measurements and validated outcome questionnaires, demonstrated that toe-to-thumb transfer is an effective procedure in restoring hand function.⁶⁶ In addition, patients did not complain of gait difficulty after either big toe or second toe transfer.

One of the most complex problems in hand surgery is the reconstruction of a hand without digits. To create a new hand capable of tripod pinch, plastic surgeons can transfer multiple toes from both feet to the hand (Fig. 109-17). This type of reconstruction can restore function to an otherwise useless hand and has allowed two farmers who were treated at one center to return to heavy farm labor.

Complex Hand Injuries

Although crush injuries to the hand are common, injuries associated with sufficient force to disrupt the structural integrity of the wrist and to sever the blood supply to the hand are uncommon events (Fig. 109-18). Because multiple structures are traumatized in injuries of this kind, a systematic treatment approach is important in salvaging the hand and in restoring its function. Crucial steps in the management of this injury are: (a) ruling out other injuries, (b) aggressive débridement, (c) skeletal fixation, (d) decompression of fascial compartments in the hand, (e) revascularization, (f) tendon repair, (g) nerve repair, and (h) early soft tissue coverage (within 1 week of injury).

Figure 109-16. A: Second-toe transfer for thumb reconstruction in a carpenter. He sustained a thumb amputation at the metacarpophalangeal joint while using a saw at work. B: Good function with restoration of fine pinch. The patient returned to work as a carpenter 3 months after the toe reconstruction.

Figure 109-17. A: A farmer who lost all his fingers when he was injured by a corn picker. A groin skin flap was used to cover the exposed metacarpal heads. B: A second toe was removed from one foot to reconstruct the thumb, and the second and third toes were removed together from the other foot to reconstruct the fingers. Note the good opposition of the thumb and acceptable flexion of the digits. The patient returned to work on his dairy farm after the hand reconstruction.

Figure 109-18. A: Accidental shotgun blast injury in a 16-year-old boy. Both the radial and ulnar arteries were ruptured, and the hand was ischemic. The wrist was destroyed, and multiple tendons and nerves were severed. B: Volar wrist wound. Markings show incision lines for ulnar artery exposure.

Ruling Out Other Injuries

In devastating trauma, attention is often focused on the obvious injury, and injuries to other organ systems may be ignored. In a review of 1,100 patients referred for emergent microsurgery over a 7-year period, investigators found 9 cases (0.8%) of unrecognized life-threatening injuries that required abandonment of the microsurgical procedures.⁶⁷ Therefore, systematic trauma evaluation and ruling out other associated injuries should precede treatment of the hand injury.

Débridement

Severe crush and blast injuries are associated with large zones of injury, and the wounds may be contaminated with foreign materials such as grease or paint, as in printing-press injuries. In these cases, aggressive débridement is important in preventing infection. Except for critical structures that include nerves and tendons, all devitalized soft tissues and bone fragments must be excised. The concept of radical débridement has been shown to decrease wound infection and improve success of microvascular reconstruction.⁶⁸

Skeletal Fixation

After débridement, the next priority is to stabilize the wrist and to rigidly fix hand fractures. A stable wrist provides a platform for repairing other injured structures. If the crush injury is associated with comminuted fractures of multiple carpal bones and rupture of the intercarpal ligaments, wrist fusion may be the best option because it is often impossible to reconstitute the normal anatomy of the distal and proximal carpal rows in face of severe comminution of the carpal bones. To avoid possible bone graft contamination with primary wrist fusion, external fixators are placed for provisional fixation during the initial débridement. Definitive wrist fusion with bone grafting is performed after adequate débridements and during the flap coverage procedure. Two 2.7-mm fixator pins are placed through an incision along the radial index metacarpal, and two proximal 3.5-mm pins are placed into the radius using an incision along the radial border of the distal radius, between the brachioradialis and the extensor carpi radialis longus. The superficial radial nerve, which lies under the brachioradialis, is dissected free and retracted away from the pins. External fixator rods are then secured to the pins with nuts and screws. If the wound is clean during the second-look procedure at 24 or 48 hours, total wrist fusion is then undertaken (Fig. 109-19). Otherwise, the external fixator is left in place until the wound is suitable for fusion using internal plating and cancellous bone grafts. This stable skeletal fixation allows early hand therapy, usually instituted on postinjury day 7 when tissue edema is subsiding.

Revascularization

In a crush injury of the wrist, the zone of injury can be extensive. Use of vein grafts is essential in performing the arterial anastomosis away from the zone of injury. The ulnar artery is chosen for repair because it is the dominant artery in most patients and because it can be exposed readily in the hypothenar area. If the ulnar artery is contused in the palm, distal anastomosis can be performed to the superficial palmar arch. Because soft tissue bridges are often present, venous outflow is not a problem and venous anastomosis is not necessary.

Decompression of Fascial Compartments

Increased edema associated with crush injuries often raises the compartmental pressures in the intrinsic muscle compartments and in the carpal tunnel. Prior reviews have shown a high incidence of ischemia and resultant fibrosis of the intrinsic muscles following crushing trauma to the hand.⁶⁹ Consequently, surgeons perform prophylactic carpal tunnel releases and intrinsic muscle decompressions in severe crush injuries of this kind.

Figure 109-19. A, B: Note destruction of the wrist joint, in addition to comminuted fractures of the distal ulna and radius. C: Total wrist fusion was performed 48 hours after the initial injury.

Soft Tissue Coverage

After aggressive débridement, a soft tissue defect is often present around the wrist. A split-thickness autograft is placed over the vein graft to prevent desiccation. Other open wounds can be covered temporarily with homografts. If wrist fusion is undertaken during the second-look procedure, primary wound closure can be achieved. For residual wound defects, split-thickness autografts are used to cover the exposed muscle bellies. However, if tendons or nerves are exposed, coverage with either fasciocutaneous or muscle free flaps will allow earlier tendon mobilization and prevent tendon adhesions. Definitive early wound coverage is important in protecting vital structures and avoiding wound colonization with bacteria (Fig. 109-20).

Nerve Repair

When nerves are crushed, the delineation between viable and nonviable nerve fascicles is difficult to assess in the acute setting. Therefore, the traditional approach is to delay the nerve grafting procedures until 2 or 3 months after injury. To prevent retraction of the nerve ends, we suture the nerve ends to the surrounding soft tissues. However, secondary nerve grafting is often difficult because of the amount of scar in the wound. One way is to primarily graft the nerve injury at the expense of more aggressive resection of the traumatized nerve ends.

Figure 109-20. A: A free rectus muscle was used for immediate coverage of the reconstructed wrist and tendons. B: The hand was salvaged, and the patient has acceptable hand function after secondary nerve and tendon reconstruction.

4 In conclusion, rigid skeletal fixation, revascularization using vein grafts, and immediate wound coverage are crucial factors in successful limb salvage.

Congenital Anomalies

Syndactyly

Syndactyly is a condition in which the fingers are fused. It can be classified as complete or incomplete. Complete syndactyly is the union of the digits extending to the distal phalanx. Incomplete syndactyly is the union of the digits proximal to the distal phalanx but distal to the normal webbing at the midproximal phalanx. Syndactyly is further categorized as simple or complex. In simple syndactyly, there is no bony union between the digits, whereas complex syndactyly includes bony union.

Typically, syndactyly can be separated when the child is 1 year of age. Surgery should be performed earlier if syndactyly affects the thumb–index finger or ring–little finger web space and causes deviation of the shorter digits during growth. Separating the fingers requires meticulous design of the skin flaps, and the dorsal skin flap is most crucial to creating a web space that is not prone to contracture (Fig. 109-21). Distally, triangular skin flaps are designed to drape the sides of the fingers. A full-thickness skin graft from the groin is often required to cover open areas in the fingers.

Figure 109-21. A: A simple, complete syndactyly in a 1-year-old child. Note the design of the dorsal skin flap to reconstruct the web space and the interdigitating distal skin flaps. B: Immediate postoperative photograph of the syndactyly release.

Figure 109-22. A: Wassel type 3 thumb duplication in a 2-year-old child. B: The radial digit was hypoplastic and was removed. C: Intraoperative picture shows the aesthetically pleasing reconstructed thumb.

Thumb Duplication

Although thumb duplication does not often cause a functional problem for the child, the presence of this prominent hand malformation can have a significant impact on the child's psychosocial development. Surgery can be undertaken when the child is about 2 years old to prevent progressive deviation of the thumb during growth. Thumb duplication can be classified into seven groups, depending on the level of the duplication. Type I consists of a bifid distal phalanx, whereas type II is a complete duplication of the distal phalanx. Types III and IV involve the proximal phalanx, and types V and VI involve the metacarpal. Type VII is triphalangeal thumb or a thumb with three phalanges. Usually the radial, less developed thumb is removed. Retention of the ulnar thumb has the added advantage of preserving the

important stabilizing ulnar collateral ligament. The surgery requires a delicate reconstruction of the bone, ligament, and tendon structures to sculpture the remaining thumb as normally as possible (Fig. 109-22). After the immediate postsurgical period, these patients are followed once a year to evaluate potential growth abnormality.

Hypoplasia and Aplasia of the Thumb

The thumb contributes about 50% of hand function and is important in pinch and grip. Reconstruction of the underdeveloped thumb is critical in improving hand function for the child. Hypoplasia of the thumb can be classified into five grades, and treatment options are often based on this classification. Grade I consists of minor hypoplasia; all components of the thumb are present, but the thumb is smaller than normal. Grade II consists of adduction contracture of the first web space and laxity of the ulnar collateral ligament at the metacarpophalangeal joint; the thenar musculature is hypoplastic but the skeletal framework of the thumb is normal. Grade III includes severe hypoplasia of the thumb with absent intrinsic muscles and underdeveloped extrinsic tendons; the skeletal framework is hypoplastic and the carpometacarpal joint is vestigial. Grade IV is characterized by a floating, nonfunctional thumb (*pouce flottant*), with soft tissue attachment of the thumb at the metacarpophalangeal joint of the index finger. Grade V is defined by total absence of the thumb. Grade I hypoplasia does not require treatment and grades III, IV, and V require index pollicization (reconstructing a thumb using the index finger) for optimal function (Fig. 109-23). In grade II, the thumb can be reconstructed by using a combination of tendon, joint, and soft tissue procedures.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a crippling disease that severely affects the quality of life for millions of Americans. RA is postulated to be an autoimmune disease mediated by inflammatory cells that attack the synovial tissues in the body. Persistent synovitis in the joints causes erosion of the articular surfaces and disrupts their soft tissue supports.

Because the hand is often damaged by RA, effective surgical treatment of hand deformities can improve patient function and restore independence. The goals of surgery for the rheumatoid hand include: (a) pain control, (b) improvement or restoration of function, (c) prevention of disease progression, and (d) aesthetic improvement. To accomplish these goals, the surgeon must have good rapport with both the rheumatologist and the patient as priorities of treatment are determined. By listening to patients with RA describe their impairments and their goals, the surgeon can gain insight into the surgical plan that will offer the patient the most benefit.

Figure 109-23. A: Absence of a thumb in a 2-year-old child. Note the floating thumb attached to the index finger. B: Immediate appearance in the operating room after pollicization. C: Three months after index pollicization, the child is able to use the new thumb for grasp and fine pinch.

Surgical treatment can be classified as preventive, corrective, or salvage.⁷⁰ Preventive procedures include tenosynovectomy to avoid tendon rupture and synovectomy to ameliorate ongoing joint destruction from erosive synovitis in the joints. Corrective procedures include tendon transfers for tendon ruptures and nerve decompression for carpal tunnel syndrome. Salvage procedures consist of joint arthroplasty and joint fusion.

A common hand deformity in RA consists of subluxation and ulnar deviation of the fingers at the level of the metacarpophalangeal joints (MPJs) (Fig. 109-24). Synovitis at the MPJs distends the joints and attenuates the supporting ligaments. Wrist destruction in RA contributes to the radial deviation of the metacarpals, which accentuates the ulnar deviation of the fingers. With progressive MPJ disease, patients have great difficulty opening their hands because of subluxation of the MPJs and difficulty with fine pinch because of the ulnar deviation of the fingers. In addition to pain at the MPJs secondary to their worn articular surfaces, RA patients often complain of the aesthetic appearance of their hands.

The Swanson metacarpophalangeal joint arthroplasty (SMPA) is an effective procedure that will meet all four goals of RA surgery. By replacing the arthritic joints with prosthetic spacers and realigning the soft tissue envelope around the MPJs, surgeons are able to markedly improve function and enhance the aesthetic appearance of RA hands. A recent systematic overview of the world's literature on this procedure showed that SMPA is an effective procedure in improving the health-related quality of life for RA patients.⁷¹

Figure 109-24. Severe destruction of the metacarpophalangeal joints with ulnar deviation of the fingers of the left hand. Note restoration of normal finger alignment of the right hand after Swanson metacarpophalangeal joint arthroplasty.

AESTHETIC SURGERY

Plastic and reconstructive surgery is a discipline that adapts broad surgical principles to a multitude of unique clinical problems by altering form and function. Plastic surgery not only restores physical function, it also enhances a patient's body image and self-esteem. In no other area of surgery is this truer than in aesthetic surgery. A blepharoplasty may not only improve the appearance of baggy, tired eyes, but also may treat visual field defects caused by eyelid ptosis or blepharochalasis. A rhinoplasty can improve the outward appearance of a nose as well as the nasal airflow and breathing.

5 Aesthetic surgery requires meticulous attention to detail, careful patient selection, rigorous procedural planning, and precise execution of technically challenging procedures. If patients are carefully selected and their goals are realistic, then the chances for a successful outcome are good. However, if a patient is poorly selected or they have unrealistic goals, then a technically successful operation with an aesthetically pleasing outcome may be a dismal failure in the eyes of the patient. The aesthetic surgeon must not only diagnose the clinical deformity, but must also carefully evaluate the patient's expectations and motivations for surgery. Through the application of sound surgical principles and technical expertise, the aesthetic surgeon can experience life-long career and personal satisfaction.

Cosmetic Procedures for the Head and Neck

Brow Lift

Brow ptosis is a natural consequence of the biologic process of aging. If left uncorrected, patients can appear angry, tired, or older than their chronologic age. If severe, brow ptosis may cause visual field obstruction on upward gaze; correction of this deformity can produce dramatic functional and aesthetic improvements. Patients frequently present with the complaint of looking tired or angry and request a blepharoplasty. In many cases, the etiology of their complaint is brow ptosis rather than upper eyelid ptosis or blepharochalasis. These patients will require a brow lift alone, or in combination with a blepharoplasty, to correct their functional and aesthetic concerns.

Correction of brow ptosis can be achieved with either an open or endoscopic approach. The traditional open approach requires a transcoronal incision with resection of excess scalp or forehead. Unfortunately, this approach results in a long scar, potential scar alopecia, and anesthesia of the scalp and forehead. In addition, an open brow lift in male patients with a receding hairline requires resection of hair-bearing scalp, which is an undesirable outcome. To reduce these complications, the endoscopic brow lift was developed and has become the primary approach for repair of brow ptosis.⁵⁴ The endoscopic brow lift requires only three to five 1-cm incisions behind the hairline to gain access to the forehead and glabellar rhytids, producing less of an aesthetic deformity and limiting the amount of scarring. There is also evidence to suggest that the endoscopic approach produces a more lasting result than the traditional approach.⁵⁵ Finally, it has been reported that anesthesia of the forehead and scalp is significantly reduced when an endoscopic approach is utilized for correction of brow ptosis, as compared to an open, transcoronal approach.

Endoscopic and open brow lifts may be performed under local or general anesthesia. Patients are marked preoperatively in the upright position. The desired brow position is at the level of the orbital

rim in male patients and 1 cm above the orbital rim in female patients. The position of the brow in relation to the supraorbital rim changes from medial to lateral; the lateral brow should be more elevated than the medial brow. During an open brow lift, a coronal incision is made and the entire forehead is mobilized in a subgaleal or subperiosteal plane down to the orbital rim. The supraorbital and supratrochlear nerves are dissected free of surrounding tissues and preserved. The corrugator and procerus muscles are resected if prominent glabellar rhytids are present. Excessive resection of the corrugator muscles will result in widening of the eyebrows in the midline. The periosteum is released at the level of the supraorbital rim when a subperiosteal plane is utilized for mobilization of the forehead; the dissection is carried down to the level of the supraorbital rim when a subgaleal plane is used for forehead mobilization. The forehead is then elevated and redraped posteriorly, the redundant scalp is resected, and the wound is closed. In an endoscopic brow lift, incisions are made within the hair-bearing scalp at the midpupillary line and over the temporal fossa. The entire forehead flap is elevated under endoscopic guidance, the procerus and corrugator muscles are resected as necessary, and the forehead is retracted posteriorly. The forehead is then secured into its new position. Various methods of forehead fixation have been described including; absorbable and nonabsorbable plates, screws, mutlipronged anchors, or cortical tunnels.^{71,72}

Postoperatively, patients are instructed to avoid vigorous physical exercise for at least 6 weeks. Bruising and swelling are anticipated for the first 2 to 3 weeks following the procedure. The final result is not expected for at least 6 to 8 weeks following the procedure.

Rhytidectomy

The deleterious effects of aging, gravity, sun exposure, and smoking are particularly evident on the face. Ultraviolet radiation and tobacco use produce fine facial wrinkling and skin laxity as a result of the loss of skin elasticity. Aging and gravity result in gradual relaxation of the facial retaining ligaments producing midfacial ptosis, deepened nasolabial folds, “jowling” along the mandibular border, and redundancy of cervical skin.⁷³ Old family photographs and driver license photographs are constant reminders of a more youthful appearance with high cheekbones, a sharp mandibular border, and smooth skin. However, as the aging process marches on, patients may lose self-confidence and self-esteem in social, political, and business situations, encouraging them to seek facial rejuvenation surgery. If the patients are selected appropriately and the surgery is carefully planned and executed, the results will be gratifying for both patient and surgeon.⁷⁴

During the preoperative evaluation, the patient’s expectations and motivations are carefully evaluated and addressed. Surgeons need to be cautious of patients whose concerns about their appearance are out of proportion to their physical deformity. Under these circumstances, a perfectly designed and performed operation may still have a dismal outcome in the eyes of the patient.

6 Patients who smoke are at a significantly increased risk for developing postoperative complications, including skin-flap necrosis, infection, or wound dehiscence, and are consequently instructed to quit prior to undergoing elective aesthetic surgery. Many surgeons will refuse to perform a cervicofacial rhytidectomy in any patient who is actively smoking or utilizing any products containing nicotine. Urine cotinine levels can be determined to confirm whether a patient has been utilizing nicotine in any form. Older patients with coexisting medical illnesses are referred to a general practitioner for optimization of their medical condition preoperatively. If the patient is deemed a moderate or high risk for general anesthesia because of medical comorbidities, then the operation may be postponed until those medical conditions are optimized. Occasionally, if the risk of anesthesia is too high for a patient, then the operation may need to be cancelled.

Younger patients (40 to 50 years old) with good skin quality, mild midfacial ptosis, and early “jowling” may benefit from a minimally invasive facelift. This operation is typically combined with an endoscopic brow lift to provide upper and lower facial rejuvenation with minimal scarring. The operation is performed under local or general anesthesia. Bilateral temporal and superior buccal sulcus incisions are made. The temporal fossa dissection is carried down to the level of the superficial layer of the deep temporal fascia. Under endoscopic guidance, the superficial layer of the deep temporal fascia is then incised to expose the temporal fat pad. The dissection then proceeds caudally until the zygomatic arch is identified. A subperiosteal plane of dissection provides access to the midface while preserving the integrity of the frontal branch of the facial nerve. The subperiosteal plane of dissection is continued into the midface with care taken to avoid the infraorbital nerves. The masseter is mobilized from its lateral attachments. The superior buccal sulcus incisions are made, and a midface subperiosteal dissection is performed under both direct visualization and endoscopic guidance. Once the dissection is

completed, the entire midface is suspended in the desired position with sutures or specialized anchors spanning from the superficial layer of the deep temporal fascia to the midface periosteum. Symmetry of the suspension is then confirmed and the wounds are closed in layers. This technique will nicely correct mild midface ptosis, mild jowling, and early nasolabial fold prominence. However, this technique will not correct deformities from significant skin laxity. Under these circumstances, a traditional cervicofacial rhytidectomy will be required.^{71,75}

In patients who require resection of excess skin, a traditional rhytidectomy can be performed under local or general anesthesia. The skin incision is made over the temporal fossa 4 to 5 cm cephalad to the root of the helix and extended caudally toward the apex of the ear. The incision is then extended anterior to the ear, behind the tragus, around the base of the earlobe into the retroauricular sulcus, across the mastoid, and caudally along the anterior hairline of the neck. The skin flap is then elevated just superficial to the superficial musculoaponeurotic system (SMAS) and platysma. This plane of dissection maintains a thin layer of subcutaneous fat on the skin flap to preserve viability, while avoiding injury to the facial nerve branches, greater auricular nerve, parotid gland, and jugular vein. The flaps are elevated medially to the nasolabial fold in the face and to the midline in the neck. Occasionally a platysmal diastasis may exist which creates platysmal banding, an obtuse cervicomental angle, and a prominent neck. Under these circumstances, a platysmal plication may be performed through a 2- to 3-cm submental incision to correct the diastasis and improve the appearance of the neck. At this point, there are many variations in how the remainder of the cervicofacial rhytidectomy is performed with the goal of repositioning all of the tissues which have migrated into dependent positions creating facial aging changes. The surgeon may simply choose to not perform any additional dissection at this point and simply reposition the skin, resect the excess skin, and close the incisions. In other circumstances, the surgeon may choose to do one of the following; SMAS plication, standard SMAS dissection, extended SMAS dissection, or deep-plane dissection. These operations are all designed to improve control of facial and cervical tightening, while reducing the tension on the skin closure. Once the dissection of the facial tissues is completed and all planes are mobilized optimally, the SMAS and platysma are placed under tension and secured to create the desired facial appearance. The skin flaps are then redraped posteriorly, the patient is examined for symmetry, and a skin resection is performed. Hemostasis is obtained through judicious use of bipolar electrocautery. The wounds are closed in layers and a pressure dressing is applied. Drains are typically used in the face and neck.⁷⁶⁻⁸⁰

Postoperatively, the patient is evaluated in the recovery room for any evidence of a hematoma or facial nerve injury. It is crucial to identify a hematoma early to avoid overlying skin necrosis. Facial nerve injuries occur in only 2% to 3% of cases. On the first postoperative day, the pressure dressings and drains are removed and the patient is examined for evidence of a late hematoma, unrecognized facial nerve injury, or compromised skin flap. Patients should expect to have significant swelling and bruising for at least 2 weeks following the procedure. The final postoperative result is not realized until approximately 6 months following the procedure (Fig. 109-25).

Blepharoplasty

Eyelid surgery may be performed to correct functional or aesthetic deformities. Excessive skin and fat of the eyelids can give the patient an angry, aged, or tired look and may cause visual field obstruction. Older patients typically present with redundant skin and fine wrinkling, whereas younger patients commonly complain of persistent bags under their eyes or fine wrinkling (“crow’s feet”) at the lateral canthus. Treatment of each clinical entity requires a unique approach based on the diagnosis and presentation.⁸¹ All patients being evaluated for blepharoplasty require a complete ophthalmologic examination preoperatively to evaluate visual acuity, upper eyelid ptosis, exophthalmos, lower eyelid laxity, and symptoms of “dry” eye. Meticulous attention to details is critical for the successful outcome of blepharoplasty surgery.⁷² If there is lower lid laxity preoperatively, and a standard blepharoplasty is performed, the patient may develop a lower lid ectropion postoperatively. Symptoms of dry eye can also be significantly worsened by a blepharoplasty. As a result it is critically important to perform a comprehensive evaluation of the health of the eye prior to performing any eyelid surgery.

Once a complete evaluation has been performed and a diagnosis has been made an operative plan can be formulated to correct the concerns of the patient. The operation can be performed under local or general anesthesia. Older patients frequently require skin excisions and removal or repositioning of orbital fat. The blepharoplasty incisions are designed preoperatively with the patient in the upright position. Local anesthesia with epinephrine is then infiltrated for pain control and hemostasis. The upper eyelid blepharoplasty then begins with an elliptical excision of upper eyelid skin and orbicularis oculi

muscle. The skin excision is designed based on the amount and location of the blepharochalasis. Very rarely will a patient require removal of fat from the upper eyelids. Excessive fat resections will produce a “hollowed-out” appearance. However, occasionally there may be a substantial amount of excess orbital fat in the upper eyelids and conservative fat resection may be helpful to achieve the desired postoperative outcome. If a fat resection is going to be performed, small openings are made in the orbital septum to gain access to the two compartments of periorbital fat. A conservative fat resection is then performed to avoid a postoperative hollowed-out appearance. The skin is then redraped and the wounds are closed in a single layer. If an upper lid blepharoplasty is being performed in conjunction with a brow lift, the brow lift should be performed first, so that the amount of excess upper eyelid skin can be determined after the brow has been elevated.

The traditional lower eyelid blepharoplasty begins with a subciliary incision. A 4- to 5-mm rim of orbicularis oculi is then preserved along the lower eyelid margin. The dissection is then carried deep to the orbicularis oculi muscle until the orbital septum is identified. The orbital septum is then divided to gain access to the three compartments of periorbital fat in the lower lid. Fat may be resected in cases of prominent herniation, but overresection must be avoided. A trend in blepharoplasty surgery has emphasized periorbital fat repositioning rather than resection. Simply repositioning the herniated periorbital fat over the inferior orbital rim, rather than resecting fat, can dramatically improve the appearance of the lower eyelids.⁸² The approach of repositioning the orbital septum medially has proven to be very helpful in eliminating tear-trough deformities. Once the periorbital fat has been resected or repositioned, the skin/muscle flap is redraped superiorly and the redundant tissue is excised. The lower eyelid wounds are closed with interrupted sutures of 6-0 silk. Ancillary procedures may also be necessary to improve the position of the lower eyelid, including a medial canthoplasty, a lateral canthoplasty, lateral canthopexy, or horizontal lid shortening. If a lower lid blepharoplasty is being performed in conjunction with a rhytidectomy, the rhytidectomy should be performed first, so that the amount of excess lower eyelid skin can be determined after the facial soft tissues have been elevated.

In younger patients, the tired appearance of the lower eyelids is commonly a result of excessive or herniated periorbital fat. A lower lid blepharoplasty through a transconjunctival approach allows removal or repositioning of the periorbital fat without an external scar. The conjunctiva is divided transversely 1 mm above the sulcus to gain access to the orbital septum. The septum is divided and the periorbital fat is removed or repositioned from all three compartments. Once again, the emphasis has been to preserve periorbital fat and simply reposition the orbital septum into a more optimal location obviating the need for fat resections. The transconjunctival incision is then allowed to heal by secondary intention, allowing rejuvenation of the lower lids without an external incision.

Figure 109-25. Cervicofacial rhytidectomy with superficial musculoaponeurotic system resection, platysma plication, submental suction-assisted lipectomy, endoscopic browlift, and bilateral subciliary lower eyelid blepharoplasty. **A, B:** Preoperative appearance. **C, D:** Postoperative appearance. Note the dramatic improvement in the appearance of her neck, flattened nasolabial folds, improved definition of the mandibular border, and improved prominence of the malar regions.

Recently, a multiplanar approach for the rejuvenation of the lower eyelids has been employed to reduce the incidence of lower eyelid ectropion postoperatively. These approaches combine both subciliary incisions for removal of excess skin and transconjunctival incision for repositioning or resection of the periorbital fat. Clinical case series from experienced plastic surgeons have demonstrated outstanding outcomes with this approach.

Postoperatively, patients are evaluated in the recovery room for corneal abrasions, changes in visual acuity, or hematomas, which may require emergent intervention. No vigorous physical exercise is permitted during the early postoperative period. Artificial tears are used to maintain appropriate lubrication. Sutures are removed 5 to 7 days postoperatively. Patients are informed that they will be bruised and swollen for approximately 2 weeks and that it will be approximately 6 to 8 weeks before the final result will be seen.

Rhinoplasty

Rhinoplasty is an exacting operation to alter the external appearance and internal anatomy of the nose. The nose may be aesthetically unappealing or functionally impaired as a result of trauma, surgery, or a congenital deformity. Clearly, many familial and ethnic traits result in a multitude of nasal appearances.

As a result, it is crucial that the patient and surgeon discuss the goals of the procedure and the likelihood of achieving those goals. The patient must have realistic expectations and be prepared for the operation both physically and mentally.

To successfully achieve the goals of rhinoplasty, a complete nasal history is obtained with particular attention paid to nasal airway obstruction, allergies, trauma, and previous surgery. A photographic analysis is performed to evaluate facial and nasal dimensions. The photographs are examined with the patient, the operative plan is discussed, and the potential structural and functional outcomes are reviewed.⁸³

Rhinoplasty may be performed under local or general anesthesia. The patient is prepared for surgery by intranasal injections of vasoconstrictors containing lidocaine and epinephrine. Topical vasoconstrictors are applied to the nasal lining and septum. The operation can be performed in an “open” or “closed” fashion. The open technique requires a transcolumellar incision extended intranasally to allow exposure of the cartilage and bones of the nose. Direct visualization of the structure of the nose allows greater precision in cartilaginous sculpting, grafting, and nasal bone repositioning. The paired lower lateral cartilages create the shape and provide the support for the nasal tip. Any deformity involving the nasal tip requires manipulations of this cartilage, including resections for a bulbous or overprojecting tip, suturing to reposition an asymmetric nasal tip, or cartilage grafting to increase tip projection. The paired upper lateral cartilages and nasal bones define the shape of the nasal dorsum and control nasal airflow. A prominent dorsal hump may require resections of both the upper lateral cartilages and nasal bones. Osteotomies of the nasal bones may be required to narrow nasal width by disconnecting the base of the nasal bones from the maxilla (Fig. 109-26). In contrast, “saddle nose” deformities may require cartilage or bone grafting to provide dorsal augmentation. Alloplastic materials have been described for use as dorsal grafts, tip grafts, or columellar struts to increase nasal projection. However, many surgeons discourage use of such alloplastic grafts due to problems with infection, extrusion, and migration producing a suboptimal result acutely or chronically. Autogenous cartilage grafts from the nasal septum, ear, or rib may also be used to improve nasal appearance or airflow. These grafts can be harvested and sculpted to create the desired cosmetic appearance of the nasal dorsum and tip. “Spreader grafts” can also be placed between the nasal septum and the upper lateral cartilage to increase the size of the internal nasal valve area, improving nasal airflow.⁸⁴ The “closed” rhinoplasty technique allows access to the nasal cartilage and bones through intranasal incisions. Many experienced rhinoplastic surgeons prefer this less invasive approach. Unfortunately, it is difficult to perform many of the complicated cartilage grafting and suturing techniques with this limited exposure.

Figure 109-26. Open tip rhinoplasty with dorsal hump reduction including cartilage and bone, cephalic scroll resection of lower lateral cartilage, nasal septal cartilage spreader grafts, and nasal osteotomies. **A, B:** Preoperative appearance. **C, D:** Postoperative appearance. Note the nice reduction in the dorsal hump, supratip break, and improved dorsal aesthetic lines. The midvault collapse has been dramatically improved.

Postoperatively, the patient is instructed to keep their head elevated and apply ice packs. An external splint is used to maintain the position of the nasal bones and cartilage for 10 to 14 days. Patients should expect nasal swelling, pain, and bruising for 2 to 3 weeks; if osteotomies are performed, the patient may also experience periorbital ecchymosis. A full year is required for complete resolution of nasal tip swelling, particularly following an open-tip rhinoplasty. Approximately 10% of primary rhinoplasty patients will require an operative revision due to dissatisfaction with the cosmetic or functional outcome; the revision rhinoplasty should not be performed for at least 1 year following the original procedure to ensure that all postoperative swelling and tissue remodeling has stabilized.

Genioplasty

Genioplasties are common plastic surgical procedures to manipulate the position of the chin and thereby improve facial appearance. Based on the design of the mandibular symphysis osteotomy, the vertical height and anterior projection of the chin can be adjusted.⁸⁵ Patients with a “weak” chin may undergo an advancement genioplasty to enhance chin projection and improve the cervicomental angle. Chin augmentation may also be accomplished with an alloplastic implant, eliminating the need for an osteotomy. Patients with a very prominent chin can undergo a reduction genioplasty where the vertical height and anterior projection can be reduced. The dental occlusion is not affected by these procedures,

but the lip position and neck appearance may be altered.⁸⁶

A complete physical examination, photographic analysis, and radiographic evaluation are performed to evaluate facial harmony and determine the extent of the advancement or reduction. Dental occlusion is carefully examined to ensure that orthognathic surgery is not required to correct chin position.

Operations are typically performed under general anesthesia, but can also be performed under local anesthesia if desired. Local anesthesia containing epinephrine is injected intraorally for hemostasis and postoperative pain control. Access to the mandibular symphysis is achieved through an inferior buccal sulcus incision. The osteotomy is measured and marked based on the preoperative photographs and lateral radiographs; the mental foramen is avoided. The bony segment is mobilized and secured in its new position with plates and screws. If an alloplastic chin augmentation is to be performed, incisions can be performed in the submental region or intraorally for placement of the implant. Postoperatively, swelling and pain persist for approximately 4 to 6 weeks. During this time, the patient should perform meticulous oral hygiene and avoid foods that may traumatize the inferior buccal sulcus incision.

Cosmetic Procedures of the Trunk and Extremities (Body Sculpting)

Abdominoplasty

Abdominoplasties encompass a wide array of surgical procedures used to correct abdominal deformities resulting from excess abdominal skin, fatty tissue, and abdominal wall laxity. Abnormalities in any of these tissue planes may produce an aesthetically unappealing abdomen. Surgical procedures are designed to correct the underlying pathology and include dermatolipectomy, liposuction, and abdominal wall plication. These procedures are often combined and tailored to fit the surgical needs and desires of the patient. It is critical to define the physical anomaly responsible for the abdominal deformity so that the appropriate operative procedure or combination of procedures can be performed.^{87,88}

A standard abdominoplasty combines a dermatolipectomy, liposuction, and abdominal wall plication to correct deformity in each of the three previously mentioned abdominal wall layers. The operation is performed under general anesthesia through a bikini-line incision extending from the cephalad margin of the pubic escutcheon to the iliac crests bilaterally. The skin incisions are made and the abdominal flap is elevated off the underlying abdominal wall fascia. A circumferential incision is made around the umbilicus to allow complete elevation of the abdominal flap up to the costal margin. The patient is then placed in a flexed position, the abdominal flap is redraped caudally, and the redundant skin is resected. If any abdominal wall laxity is identified along with the skin redundancy, then a vertical, midline abdominal wall plication is also performed. Occasionally, suction-assisted lipectomy (SAL) is performed at the time of abdominoplasty to help recontour the abdomen and flanks. However, aggressive SAL of the abdominal flap may critically compromise flap vascularity and contribute to flap necrosis. Occasionally it is helpful to perform SAL along the lateral and posterior iliac crests bilaterally to reduce the prominence which may have developed following the anterior dermatolipectomy and caudal repositioning of the skin flap. A small incision is then made in the midline of the abdomen at the level of the iliac crests for delivery of the umbilicus into its new position. Closed-suction drains are placed prior to wound closure (Fig. 109-27).

A “mini-abdominoplasty” is used to treat mild abdominal skin redundancy and abdominal wall laxity. The same approach is used as previously described for a standard abdominoplasty except the skin incision is limited to the central portion of the abdomen. A limited skin resection can be performed through this approach along with an abdominal wall plication. SAL can be used in combination with this procedure if necessary.

Endoscopic abdominoplasty can be used to treat abdominal wall laxity (i.e., postpartum rectus diastasis) and localized collections of fatty tissue. Patients who are candidates for this operation must have good skin quality and only mild to moderate lipodystrophy. The endoscopic abdominoplasty is performed through two incisions, a 3- to 5-cm transverse incision within the pubic hair and a circumferential incision around the umbilicus. These incisions function as the two access ports through which the endoscopic instruments are passed. The entire abdominal wall is then elevated off of the abdominal wall fascia under endoscopic visualization with electrocautery. The midline of the abdominal wall is plicated from pubis to xiphoid. The abdominal wall is then recontoured with SAL, which is performed through the two access ports.⁶⁵

Liposuction

Liposuction is a surgical procedure designed to resect collections of fat from isolated anatomic regions. It is not a form of weight loss and is not indicated in obese patients. Liposuction is ideally suited to

patients who are within 20% to 30% of their ideal body weight and have localized collections of fat that are refractory to dietary modifications and exercise. A complete evaluation of skin elasticity is very important in patients considering liposuction because once fat is surgically removed, the skin must be able to contract down to the contour of the remaining subcutaneous tissue. If the skin quality is poor, then wrinkling, dimpling, or skin ptosis may severely compromise the aesthetic result.⁸⁷⁻⁹⁰

Figure 109-27. Mastopexy, abdominoplasty, and rectus abdominis plication. **A, B:** Preoperative appearance of breasts. **C–E:** Preoperative appearance of abdomen. **F–H:** Postoperative appearance. Note the dramatic improvement in the appearance of the breasts and abdomen. The abdomen is flat with a narrowed waistline.

Two forms of liposuction are currently used: SAL and ultrasonic assisted liposuction (UAL). SAL is used in all areas of the body but may not be as effective as UAL in more fibrous anatomic regions such as the flank, upper abdomen, or male breast. Treatment of lipodystrophy in these regions is more effective with UAL alone or UAL in combination with SAL.^{87,91} A number of technologic advances have led to new techniques for performance of liposuction or liposculpting (i.e., lipodissolve, endermologie, and Smart-lipo). However, none of these newer devices or techniques has proven to be clinically efficacious in rigorous clinical trials, nor have they been shown to be as effective as Standard SAL or UAL.

As with all aesthetic procedures, careful patient selection is of paramount importance. All patients must undergo a complete evaluation preoperatively to ensure that their goals can be achieved by performance of liposuction. Preoperative photographic documentation is performed on all patients. Markings are then made with the patient in the upright position. Access ports (6 to 8 mm), through

which the SAL or UAL is performed, are marked in concealable areas. Patients can undergo these procedures under local or general anesthesia. Tumescent fluid (1,000 mL of LR, 50 mL of 1% lidocaine, and 1 mg of epinephrine) is then infiltrated for pain control and hemostasis.

SAL is performed with metal cannulas connected to an aspirating device that generates a negative pressure of 1 atmosphere. Various cannula configurations are used to perform the resection. Fatty tissue is aspirated into the holes of the cannula and then resected by movement of the cannula tip. The operation is performed through multiple access ports, starting with large (6- to 8-mm diameter) cannulas and progressing to smaller (3- to 4-mm diameter) cannulas with fewer holes to allow more precise body contouring. Overlapping patterns of resection are used to avoid contour irregularities.

UAL is a surgical technique that allows body contouring through the liquefaction and aspiration of fatty tissue. When employed alone or in combination with traditional SAL, UAL is effective for treating lipodystrophy in fibrous anatomic regions such as the flank, upper abdomen, and male breast. The UAL probe tip produces sound waves at an ultrasonic frequency of 20 to 30 kHz. The sound waves cause cavitation which disrupts lipocytes. Low-power suction is then employed to remove the resultant fluid. If UAL is used inappropriately, patients may experience severe complications, including full-thickness skin loss from thermal injury.⁹¹

All patients are placed in a compressive garment 24 hours per day for 6 weeks postoperatively. Early postoperative compression reduces the chances of hematoma formation. Prolonged compression reduces swelling and the potential for skin wrinkling. All patients experience some degree of ecchymosis, swelling, and decreased sensibility. The end result will not be realized for approximately 2 to 3 months following the procedure.

PEDIATRIC PLASTIC SURGERY

The specialized area of pediatric plastic surgery focuses on the reconstruction of abnormalities in children with congenital malformations and acquired deformities. Utilizing a sound knowledge of embryology as well as the changes inherent during growth and development, pediatric plastic surgeons employ a combination of innovation and technical expertise to restore both form and function to their patients. Although the manifestations of congenital malformations may be diverse, the approach to reconstruction is always based on solid fundamental surgical principles. Similarly, the management of traumatic or other acquired maladies in the pediatric population is founded on essential surgical tenets influenced by the special considerations of maturation and growth. This section concentrates on the most salient aspects of pediatric plastic surgery to give the clinician an accurate grasp of the subspecialty.

Cleft Lip and Palate

Perhaps the area of expertise that best exemplifies the specialty of pediatric plastic surgery is the management of children with cleft lip and palate deformity. The cleft lip and palate pose a variety of structural and functional deficits that must be addressed with respect to growth and development as well as psychosocial concerns of the individual patient and family. The care of these children requires exacting surgical technique in combination with the efforts of a team of allied health professionals to effect a comprehensive level of rehabilitation.

The overall incidence of cleft lip and palate deformity is approximately 1 in 750 children. This incidence is significantly higher in the Asian population, 1 in 300, and significantly lower in the black population, 1 in 2,000.⁹²⁻⁹⁵ The distribution of cleft types is approximately 46% combined cleft lip and palate, 21% isolated cleft lip, and 33% isolated cleft palate.⁹⁵ Almost 30% of children with cleft lip and palate deformity have associated birth defects that vary in scope and extent and therefore require vigilance in the physical examination.⁹⁶ The chance of having a second child with cleft lip and palate to unaffected parents is approximately 4% as is the chance of one affected parent producing an offspring with a cleft.^{97,98} Genetic counseling is usually helpful in both educating the parents and screening for other associated congenital anomalies.

Figure 109-28. Left unilateral complete cleft lip.

7 A cleft lip deformity can be bilateral or unilateral and is considered *complete* if it extends into the nose and *incomplete* if it does not (Fig. 109-28). The cleft lip can extend into the gum partially or completely through the alveolus, creating a bony defect. The cleft lip deformity affects the nose as well as the lip, and therefore both of these structures must be addressed in the reconstruction of the deformity. Although the timing of cleft lip repair is controversial, the repair of the cleft lip is most often addressed in about the third month of life, after the child shows sufficient weight gain. This timing permits a potentially safer anesthetic administration.

There are multitudes of cleft lip repairs, but the goals of the repairs remain the same: an anatomic reconstruction with minimal scarring and normal function. In general, the skin around the cleft is cut into flaps that are brought together in a way that will give adequate length to the lip and restore the continuity of the orbicularis musculature (Fig. 109-29).⁹⁹ Long-term symmetry is the goal of reconstructive procedures to the cleft lip–nasal deformity, and taking into account how the face changes with growth is necessary to execute the appropriate operation in infancy.⁹⁶

The cleft palate can affect the soft palate alone or include the hard palate. Victor Veau classified the degree of clefting I to IV from the least severe (soft palate only) to most severe (through the soft palate, hard palate, and alveolus bilaterally) (Fig. 109-30).¹⁰⁰ In some cases, a cleft palate may have no mucosal separation at all and display only a separation or clefting of the underlying musculature. This special situation is referred to as a submucous cleft palate and may also have functional consequences for the patient. Functionally, the hard palate acts as a structural barrier between the oropharynx and the nose. The soft palate moves superiorly and articulates with the posterior and lateral pharyngeal walls to create a seal between the oropharynx and the nasopharynx during speech and swallowing. The coordinated activity of the soft palate prevents regurgitation of solids and liquids into the nose while eating and prevents hypernasal speech while producing strictly oral sounds. As with cleft lip, there are a multitude of cleft palate repairs but the goals of the repairs remain the same: repositioning the abnormal anatomy and creating normal function. Reconstructive procedures are based on reconstituting the oral and nasal lining of the palate and reapproximating and realigning the palatal musculature. A purely soft palatal cleft may require only the separation of the layers of the palate, reorientation of the muscles, and simple closure. The wider clefts and many of the hard palatal clefts, however, require relaxing incisions and release of the mucosa from the underlying bone. The lateral mucosa from both sides is transposed over the midline cleft and sewn closed. The addition of double-opposing Z-plasties in the velum adds further length to the palate (Fig. 109-31).¹⁰⁰ Flaps derived from the vomer may be required to achieve closure without tension, a chief precept for any repair of the palate. Many children with this deformity exhibit growth restriction of the midface and bony palate, which is thought to be due to the dissection of mucosal tissue off the bone.¹⁰¹ Delaying palate closure until the maxilla has finished growing allows better facial growth, but leads to poor speech outcomes, whereas early intervention is thought to improve speech. For this reason, the timing of the repair of the cleft palate is controversial; however, the cleft palate repair is most often addressed by the age of 1 year.

Figure 109-29. A: Markings. B: Dissection of the orbicularis muscle and rotation of the central (greater segment) and advancement of the lateral (lesser segment). C: Appearance of the closure.

Figure 109-30. Veau classification of cleft palate. A: Veau I involves the soft palate only. B: Veau II involves the soft palate and hard palate up to the incisive foramen. C: Veau III involves the soft and hard palate and is through the alveolar ridge. D: Veau IV, the most severe, involves the soft and hard palate and the premaxilla is discontinuous with the alveolar arch.

Speech therapy is almost always required for children with a cleft palate and is instituted as soon as the child develops the necessary language skills. Early intervention programs have arisen for preschoolers, and speech programs are often available through local school systems. Unfortunately, the palate repair alone is successful in normalizing speech in only about 80% of patients.¹⁰² The remainder of patients will require a supplemental operation to decrease residual hypernasality and improve speech. The operations directed at salvaging speech are performed early enough to have the most beneficial effect on speech development, while giving adequate time to ensure that the patient has been given ample opportunity for speech therapy to maximize the potential of the palate repair. The decision to operate is based on a perceptual analysis of speech and is aided by visualization of palatal function with nasoendoscopy and objective measures of function using nasometry techniques. Techniques vary, but the operative procedures are based on placement of either dynamic or static tissue near the velopharyngeal port to better regulate and impede the abnormal flow of air into the nasopharynx.

Orthodontics is a key portion of the comprehensive restoration of the cleft patient and requires close interaction between the pediatric plastic surgeon and the orthodontist. One of the early interactions involves the repair of any residual clefting of the alveolus. Bone grafting is required for reconstruction of the alveolar cleft to restore the continuity of the upper maxillary dental arch, allow the normal emergence of the canine tooth, close the persistent oral nasal fistula, and provide structural support for the recessed nasal alar base. The orthodontist will monitor tooth eruption and may institute early-phase therapy to align the teeth in preparation for bone grafting. The timing of alveolar bone grafting is also controversial but is mandatory for normal tooth emergence. Bone grafting is often performed at about 7 to 8 years of age and entails the surgical isolation and repair of the oral nasal fistula, the reconstruction of the adjacent nasal floor and palatal roof, the placement of bone graft in the alveolar defect, and

coverage anteriorly with gingival flaps. Cancellous bone grafts harvested from the iliac crest is used most commonly. To eliminate the donor site, other bone substitutes have been trialed, with studies using recombinant human bone morphogenic protein (rhBMP2) showing promise¹⁰³; however, iliac bone graft currently remains the standard of care.

Many patients respond favorably to the skilled implementation of a long-term orthodontic plan, but some patients display bony hypoplasia as mentioned earlier and require orthognathic surgery of the maxilla, and possibly the mandible, to assist in establishing normal occlusion. Operations to restore a normal occlusion should await the cessation of growth so that the surgical registration of occlusion will be permanent and not require additional procedures. The most common operation to address midfacial hypoplasia and restore occlusion in the cleft patient is the Le Fort I osteotomy. The orthodontist helps the pediatric plastic surgeon to determine the best postoperative occlusion for the patient based on the orthodontic plan, and an oral surgical splint is fashioned to allow easy registration intraoperatively. The patient undergoes a horizontal osteotomy above the level of the tooth roots and across the nasomaxillary and zygomaticomaxillary buttresses below the level of the zygomatic body (Fig. 109-32). The bones of the midface are separated from the cranial base by performing a pterygomaxillary disjunction, and the floating maxilla is then repositioned into the planned occlusion by registering the teeth in the splint. The bones of the maxilla are then fixed using plates and screws. In severe malocclusion cases, the mandible may also need to be cut and moved into a position that results in an anatomic orthognathic bite.

Figure 109-32. Le Fort I osteotomy in an advanced position. One side has been plated into position.

The last operation to be performed on the patient with a cleft lip and nasal deformity is often the formal rhinoplasty. There is almost always septal deviation that must be addressed in these patients and is an important part of the procedure. Each rhinoplasty is necessarily individualized, but the procedure usually entails repositioning and trimming of the nasal tip cartilages, added support to the nasal tip and slumping lower lateral cartilages to achieve projection, straightening of the septum, and finally infracturing of the widened nasal bones.

Although the care of the cleft patient requires interaction with the pediatric plastic surgeon and the cleft team throughout the patient's childhood, it should remain a small and unobtrusive part of life. The number of operations is kept to the minimum needed to attain an adequate reconstruction as deemed

necessary by both the patient and the surgeon. Revisional surgery is usually an important part of cleft care but should be guided by the principle that the intervention is done *for* the child and not *to* the child, with an attempt to empower the patient as often as possible.

Craniosynostosis

8 Craniosynostosis is defined as the premature fusion of one or more of the cranial sutures. The child afflicted with craniosynostosis displays abnormalities in the size and shape of the cranial vault. Virchow law states that the growth of the skull will be restricted in the direction perpendicular to a synostosed suture while compensatory growth occurs in a parallel direction.¹⁰³ The ensuing skull shape of the patient provides the nomenclature of the deformity and is primarily empiric in nature (Fig. 109-33). Synostosis of the metopic suture most often results in a triangular forehead and is referred to as *trigonocephaly*. Unilateral coronal suture involvement often results in a recessed or slanted supraorbital bar and forehead and is referred to as *plagiocephaly*, whereas bilateral coronal synostosis often results in a shortened and flattened forehead referred to as *brachycephaly*. The sagittal suture is the most commonly fused suture and results in a boat- or keel-shaped head referred to as *scaphocephaly*.

Figure 109-33. A: Turribrachycephaly (short, flat head). B: Plagiocephaly (slanted head). C: Trigonocephaly (triangular head). D: Scaphocephaly (keel-shaped head).

Figure 109-34. A: Plagiocephalic head viewed from above. B: The surgeon removes the bone of the forehead and advances the forehead to allow the brain to grow and the skull to resume a normal shape.

The abnormal shape of a synostotic cranium can often be severe and progressively worsens as the

brain continues to grow and expand in the wrong dimensions. In addition, a small percentage of patients with a single-suture synostosis, and a much larger percentage of children with multiple-suture synostosis, are at risk for the development of increased intracranial pressure.^{105,106} The care of these patients, therefore, requires close interaction between a pediatric neurosurgeon and a pediatric craniofacial plastic surgeon. A thorough clinical evaluation is mandatory and an ophthalmologic evaluation to check for papilledema can be beneficial. A CT scan is also useful in these patients to confirm the diagnosis and assess the ventricular system as well as the neuroanatomy for possible associated developmental anomalies of the brain.

Once the functional aspects of craniosynostosis are evaluated and addressed, the operative strategy is then aimed at restoring normal morphology. The operation is tailored to the individual diagnosis and malformation, but the underlying surgical principles remain the same. A sinusoidal coronal incision in the scalp is used to afford access to the cranium and to hide the scar. The pediatric neurosurgeon performs a craniotomy to provide access to the cranial vault. In the case of plagiocephaly and trigonocephaly, the craniofacial pediatric plastic surgeon removes the frontal bar by performing a bilateral osteotomy at the lateral orbital rim, and along the orbital roof meeting in the midline with a cut across the region just above the glabella. The frontal bar is removed, reshaped, and replaced in an advanced position with bone grafts placed to support the reconstruction. The bones of the forehead are similarly cut, bent and reshaped, and placed into a normal anatomic position. The bones are fixed with resorbable plates and screws (Fig. 109-34). A gap is left in the area of the coronal suture to allow growth and expansion of the brain. During infancy the dura is osteogenic and fills the gap in slowly with newly formed bone. In the case of a sagittal synostosis, the frontal bar often need not be removed; the operation entails removing and remodeling the majority of the calvaria, increasing the biparietal distance and decreasing the anteroposterior distance, leaving areas posteriorly open to encourage growth in that direction. This arrangement encourages subsequent growth to fill out the parietal region and create a more anatomic shape. Another common approach to treating sagittal craniosynostosis is the endoscopic strip craniectomy whereby the synostosed suture and a few centimeter margin of bone on either side are removed. This is followed by approximately 8 to 12 months of helmeting to coax the head into the correct shape. In syndromic craniosynostosis patients, such as those with Apert, Crouzon, or Pfeiffer syndrome, similar reconstructions are required for the cranial vault. Additional operations are often needed to address deformities of the orbits and midface. In contrast to the midfacial hypoplasia exhibited by the cleft patient, the patient with syndromic craniosynostosis has a much more severe and extensive deformity and therefore requires more involved operations. Le Fort III and monobloc advancements move the entire upper and midfacial region forward and can be used to vastly improve the appearance of the patient while establishing a more normal functional anatomy (Fig. 109-35). These operations address the bulging eyes, malar hypoplasia, and recessed and diminutive nasopharyngeal airway of these patients, restoring normal eye position and opening up the breathing passages to relieve obstructions of the airway and symptoms of sleep apnea.¹⁰⁷

Hemangiomas and Vascular Malformation

The pediatric plastic surgeon is often the primary care giver for children afflicted with cutaneous hemangiomas and vascular malformations. These lesions may present at birth or in the neonatal period and require careful diagnosis and management. Hemangiomas are benign tumors that most often arise just after birth and undergo a spontaneous rapid growth phase followed by a slow involutinal stage.¹⁰⁸ In general, acute management of hemangiomas is nonoperative. After the involutinal phase is complete some patients will require excision of the fibrofatty residuum, usually before school age (Fig. 109-36). Ulceration or interference with function may prompt intervention. The use of local or systemic steroids can arrest the proliferative phase. Propranolol has recently been shown to effectively halt the growth of these vascular tumors and is replacing steroids in popularity.¹⁰⁹ Rarely hemangiomas require early excision and in such cases operative strategies should strive to conserve tissue and function, avoiding the creation of significant deformities that would necessitate extensive and delayed reconstruction.

Vascular malformations are comprised of arteries, veins, capillaries, lymphatic vessels, or a combination of each. The malformations are present at birth and grow in proportion to the patient. As opposed to vascular tumors (e.g., hemangiomas) vascular malformations do not grow rapidly nor spontaneously involute. Superficial capillary malformations (“port-wine stains”) respond well to pulsed-dye laser therapy. Venous malformations, lymphatic malformations and lymphaticovenous malformations can often be managed with sclerotherapy or intralesional laser treatment. Larger lesions are often infiltrative, and staged partial excisions can be performed if there are functional indications for intervention. Arteriovenous malformations can be the most vexing to treat as no options that ensure eradication exist.

Nevi

Congenital nevi are the most common benign tumor seen by the pediatric plastic surgeon. The small- to moderate-sized nevi are usually of little consequence but need to be monitored closely for any

significant changes in size, shape, color, bleeding, or ulceration. The potential for degenerative malignancy into a melanoma for small- to moderate-sized congenital nevi is controversial.¹¹⁰ Serial examination and even photographs can be helpful to document changes over time, and the gold standard for any doubtful skin lesion is still excisional biopsy.

Figure 109-37. Fully expanded tissue expanders in preparation for excision of a congenital melanocytic nevus.

Giant congenital melanocytic nevi are larger and less common, but they can be devastating to a child and the family. These lesions can affect the entire body or vast areas, including vital structures such as the eyelids, anus, and genitalia. Although the risk of malignancy is higher in these patients, operations have not shown to decrease that risk, hence a reasoned and conservative approach to such difficult cases is mandatory.^{111,112}

It is often helpful to enlist the aid of a dermatologist and the patient's pediatrician to assist in monitoring these lesions. Again, photographic documentation is helpful in serially assessing these lesions. Areas that show significant change warrant incisional biopsy and pathologic evaluation. The aesthetic consequences of these lesions often can be severe, and parents often want them to be excised. The surgical approaches to benign giant congenital melanocytic nevi are varied and range from excision and grafting to serial excision as well as the use of tissue expansion.

The use of extensive skin grafting as a reconstructive option for the reconstruction of giant hairy congenital nevi is usually reserved for malignant or dysplastic lesions. Skin grafts are not a particularly durable long-term cover, and they are often aesthetically displeasing and require subsequent resection and reconstruction. Serial excision can be useful in limited giant hairy congenital nevi, especially in locations near tissues that stretch well. The tissues adjacent to the lesion are undermined and advanced over the nevus to determine the amount that can be resected, and then a portion of the nevus is excised and the tissues are then reapproximated and allowed to heal. After 4 to 6 months the same procedure is performed until the nevus is fully excised. Tissue expansion requires the placement of a tissue expander adjacent to the lesion with slow instillation of saline into the expander over time, allowing stretching and recruitment of new tissue near the nevus to assist in excision and closure (Fig. 109-37). The quality and thickness of the skin, the possibility of exposure and infection, and the cooperation of the young patient at times limit the usefulness of this technique.

Prominent Ears

Prominent ears are a deformity that is mainly in the domain of the pediatric plastic surgeon. Children with prominent ears are prone to ridicule by classmates in school, teasing by siblings, and thoughtless comments by insensitive adults. The deformity does not usually present with an enlarged ear but rather with a lack of an antihelical fold, either with or without conchal hypertrophy. An incision is made on the posterior portion of the ear exposing the cartilage, and sutures are placed in a mattress fashion to reconstruct an antihelical fold. The stiff conchal cartilage can be weakened, and the concha is then secured to the mastoid fascia using permanent suture. A strict postoperative headbanding protocol may be used to avoid trauma to the ear and allow undisturbed healing. Successful otoplasty is one of the most rewarding procedures performed by a pediatric plastic surgeon because the child usually wants the surgery and is rewarded with immense satisfaction.

Myelomeningocele

The interaction between the pediatric neurosurgeon and the pediatric plastic surgeon often extends beyond the realm of craniofacial surgery. A prime example of the symbiotic interaction between the two specialties is in the repair and reconstruction of the myelomeningocele which is a form of spina bifida. The neurosurgeon is often presented with an exposed dural sac and a wide-open skin defect. The neurosurgeon may be faced with a tenuous dural closure and may need to resort to the use of a homograft to achieve an adequate dural repair. The pediatric plastic surgeon can assist by closing the defect over the dural reconstruction with stable, reliable coverage using well-vascularized tissue, protecting the neurosurgeon's repair. The soft tissue coverage may require local paraspinous muscle flaps or various fasciocutaneous flaps, but the goal of a durable reconstruction with a normal contour is paramount so as to avoid persistent long-term complications both at the level of the skin and at the level of the dural repair ([Fig. 109-38](#)).

SUMMARY

Although there are a multitude of additional procedures and topics in the specialized domain of the pediatric plastic surgeon, such as pediatric facial trauma, facial reanimation surgery, and various deformities resulting from congenital hypoplasia and hyperplasia, this chapter has focused on some of the major and more common areas of patient management. In fact, the pediatric plastic surgeon is often a chief collaborator with many of the pediatric surgical services when presented with a case of challenging wound care or any case which poses a reconstructive dilemma. Continuing innovation and technical advances combined with an appreciation for sound fundamental surgical principles allow the specialty to continue meeting that challenge.

Part One Scientific Principles	41
1 Lifelong Learning	42
2 Principles of Intermediary Metabolism	50
3 Surgical Nutrition and Metabolism	69
4 Obesity and Metabolic Disease	103
5 Wound Healing	120
6 Hemostasis	142
7 Inflammation	169
8 Surgical Infections	235
9 Shock	265
10 Critical Care	296
11 Fluids, Electrolytes, and Acid–Base Balance	337
12 Burns	370
13 Anesthesiology and Pain Management	411
14 Oncology	446
15 Preoperative Risk Assessment	483
16 Measuring the Quality of Surgical Care	519
17 Policy Approaches to Improving Surgical Quality	529
18 Patient Safety	536
Part Two Surgical Practice	549
SECTION A: TRAUMA	550
19 Trauma and Trauma Care: General Considerations	551
20 Prehospital and New Advances in Resuscitation	576
21 Head Trauma	588
22 Maxillofacial Injuries	614
23 Neck Injuries	629
24 Thoracic Trauma	642
25 Abdominal Trauma	655
26 Genitourinary Trauma	687
27 Vascular Trauma	699
28 The Principles of Orthopedic Surgery for Trauma	717
29 Pediatric Trauma	734
30 Geriatric Trauma	760
31 Trauma in Pregnancy	775
32 Postinjury Management	787
33 Environmental Injuries	802
SECTION B: TRANSPLANTATION	839
34 Clinical Transplant Immunology	840
35 Organ Procurement and Preservation	860
36 Renal Transplantation	875
37 Hepatic Transplantation	892
38 Cardiac Transplantation	924

39 Pulmonary Transplantation	942
40 Pancreas and Islet Transplantation	978
SECTION C: HEAD AND NECK	1012
41 Head and Neck	1013
SECTION D: ESOPHAGUS	1037
42 Esophageal Anatomy and Physiology and Gastroesophageal Reflux Disease	1038
43 Esophageal Tumors and Injury	1106
SECTION E: STOMACH AND DUODENUM	1145
44 Gastric Anatomy and Physiology	1146
45 Gastroduodenal Ulceration	1163
46 Management of Obesity	1183
47 Gastric Neoplasms	1204
SECTION F: SMALL INTESTINE	1229
48 Anatomy and Physiology of the Small Intestine	1230
49 Ileus and Bowel Obstruction	1247
50 Crohn Disease	1287
51 Small Bowel Tumors	1316
SECTION G: PANCREAS	1336
52 Pancreas Anatomy and Physiology	1337
53 Acute Pancreatitis	1365
54 Chronic Pancreatitis	1383
55 Neoplasms of Exocrine Pancreas	1397
56 Neoplasms of the Endocrine Pancreas	1425
SECTION H: HEPATOBILIARY AND PORTAL VENOUS SYSTEM	1451
57 Hepatobiliary Anatomy	1452
58 Hepatic Infection and Acute Liver Failure	1472
59 Cirrhosis and Portal Hypertension	1493
60 Hepatic Neoplasms	1545
61 Calculous Biliary Disease	1576
62 Biliary Injuries and Strictures and Sclerosing Cholangitis	1604
63 Biliary Neoplasms	1631
SECTION I: COLON AND RECTUM	1659
64 Colon and Rectal Anatomy and Physiology	1660
65 Acute Gastrointestinal Hemorrhage	1678
66 Ulcerative Colitis	1708
67 Colonic Polyps and Polyposis Syndromes	1725
68 Colorectal Cancer	1760
69 Diverticular Disease	1829
70 Anorectal Disorders	1846
71 Diseases of Appendix	1888
SECTION J: HERNIA AND SPLEEN	1910
72 Abdominal Wall Hernias	1911
73 The Spleen	1982
SECTION K: SURGICAL ENDOCRINOLOGY	2030
74 Breast Disease	2031
75 Thyroid Gland	2112
76 Parathyroid Glands	2146
77 Adrenal Gland	2180
78 Pituitary Surgery	2208
SECTION L: LUNG	2230
79 Lung Neoplasms	2231

80 Non-Neoplastic Thoracic Disease	2277
SECTION M: VASCULAR DISEASE	2325
81 Congenital Heart Disease	2326
82 Valvular Heart Disease and Cardiac Tumors	2364
83 Ischemic Heart Disease	2386
84 Mechanical Circulatory Support for Cardiac Failure	2418
85 Thoracic Aortic Aneurysms and Aortic Dissection	2448
86 Pericardium	2469
87 Vascular Diagnostics: The Noninvasive Vascular Laboratory	2483
88 Vascular Infection	2523
89 Cerebrovascular Disease	2544
90 Upper Extremity Arterial Disease	2569
91 Renal and Splanchnic Vascular Disease	2583
92 Aortoiliac Disease	2623
93 Peripheral Arterial Disease	2645
94 Lower Extremity Amputation	2673
95 Thoracoabdominal Aortic Aneurysms	2693
96 Abdominal Aortic Aneurysms	2716
97 Lower Extremity Aneurysms	2776
98 Venous Disease	2791
SECTION N: PEDIATRIC SURGERY	2841
99 Fetal, Neonatal, and Pediatric Physiology	2842
